Abstract

This paper develops and evaluates empirically the implications of a theoretical model of an open economy in which variations in both trade openness and capital mobility can influence the sacrifice ratio. Key predictions forthcoming from the model are that both forms of globalization can independently affect the capital ratio, once the influences of the level of central bank independence and the degree of wage stickiness in nations' economies are taken into account. Examination of cross-country data encompassing 58 disinflations for 16 countries yields evidence consistent with these essential predictions of the theoretical framework.

TRADE OPENNESS, CAPITAL MOBILITY, AND THE SACRIFICE RATIO

1. Introduction

The path-breaking work of Romer (1993) highlighted an apparent inverse relationship in cross-country data between the degree of openness to international trade and the inflation rate. Romer's suggested explanation for this relationship is that increased trade openness exposes a nation to greater negative terms-of-trade effects resulting from domestic output expansions, thereby reducing the incentive for a central bank to engage in inflationary policymaking. Lane (1997) supplemented this rationale by proposing that increased trade openness reduces the potential output gains from unexpected inflation in non-traded-goods sectors characterized by imperfect competition and sticky product prices. In addition, Karras (1999) argued that greater indexation of nominal wages to unexpected inflation in response to increased trade openness could also reduce the incentive for central banks to inflate.

Temple (2002), however, questioned the relevance of explanations relying on a presumption that increased trade openness reduces the sacrifice ratio, because analysis of cross-country data failed to reveal such a relationship. Indeed, Daniels, Nourzad, and VanHoose (2005) have recently offered evidence indicating that once the role of central bank independence is considered, increased trade openness is associated with an increase in the sacrifice ratio, a result consistent with the analysis of Rogoff (2006), enunciations of some policymakers, such as Bean (2006), and evidence provided by Duca and VanHoose (2000) indicating that increases in product-market competition from both domestic and international sources have contributed to a shallower U.S. Phillips curve. This finding is obviously at odds with a standard Barro-Gordon (1983) interpretation, although Daniels and VanHoose (2006) have provided a theoretical rationale for how increased trade openness could both raise the sacrifice ratio and reduce equilibrium inflation when imperfectly competitive product markets are

included in an open-economy Barro-Gordon analysis. Furthermore, Bowdler (2004) suggests that the nature of the trade openness-sacrifice ratio relationship may depend on the exchange-rate regime that is in place.

Separately, an additional line of research has focused on the other key aspect of globalization, capital mobility, and its relationship with both the sacrifice ratio and inflation. Gruben and McLeod (2002, 2004) suggest that increased capital mobility may act as a policy commitment mechanism that yields lower equilibrium inflation and present evidence supporting a disinflationary role for higher capital mobility. At the same time, however, work by Razin and Yuen (2002), Loungani, Razin, and Yuen (2001), and Razin and Loungani (2005) has suggested a positive relationship between capital mobility and the sacrifice ratio—again, a result inconsistent with a narrow Barro-Gordon-style interpretation. As a rationalization of how greater capital mobility could simultaneously contribute to lower inflation while increasing the sacrifice ratio, Razin and Loungani suggest that globalization may have boosted policymakers' loss weight on inflation and thereby induced lower equilibrium inflation.

Clearly, there remains a wide array of views regarding the effects of globalization on the sacrifice ratio and the relationship between these effects and the trade openness-inflation and capital mobility-inflation relationship. Some have, for instance, questioned whether the trade openness-inflation relationship either may be illusory, as suggested by Terra (1998), or may have shifted or even broken down since the early 1990s, as argued by Bleaney (1999). Indeed, Ball (2006) questions whether there is sufficient evidence to conclude, at least for the United States, that either trade openness or capital mobility is related to either the sacrifice ratio or inflation.

In light of these conflicting views, further exploration of the effects of greater trade openness and capital mobility is clearly warranted. In this paper, our objective is to investigate the *separate and combined* effects of both potential manifestations of globalization—increased trade openness and greater capital mobility—on the sacrifice

ratio. We develop a simple open-economy model that incorporates both openness to trade and the mobility of capital, and we analyze its predictions regarding effects of both forms of globalization on the sacrifice ratio. As emphasized with respect to trade openness by Daniels and VanHoose (2006) and with regard to capital mobility by Loungani, Razin, and Yuen (2001), the extent to which nominal rigidities are a prevalent feature of a nation's economy has a critical bearing on how globalization affects the sacrifice ratio. Thus, we utilize a model in which a portion of firms utilizes nominal wage contracts and in which remaining firms do not.

Our consideration of wage contracts as a source of nominal rigidity differs from the recent emphasis on price stickiness in much of the recent literature. In part, this choice is based on evidence that nominal wage rigidities are an important factor in the openness-inflation relationship (see Daniels, Nourzad, and VanHoose, 2006). More generally, however, this choice reflects our fundamental agreement with Cukierman (2004), who argues out that adding product-price stickiness to input-price stickiness arising from nominal wage contracts ultimately adds little of fundamental importance to the nature of analysis of trade-offs faced by policymakers.¹ Indeed, consistent with Cukierman's point, our model yields sacrifice-ratio implications for firms utilizing nominal wage contracts that are analogous to those obtained by Razin and Yuen (2002), Loungani, Razin and Yuen (2001), and Razin and Loungani (2005) in their sticky-price-based analyses of the openness-sacrifice ratio relationship. Nevertheless, our inclusion of firms that face no direct nominal wage rigidities—but which nonetheless confront spillovers created by nominal wage rigidities at other firms in the economy, as in Duca (1987) and Duca and VanHoose (2001)—allows for partial price adjustment that generalizes our analysis of the effects of greater capital mobility and its interaction with impacts of increased trade openness.

The next section presents our theoretical framework, and section 3 investigates its implications for the relationships among trade openness, capital mobility, and the

sacrifice ratio. Section 4 explores the empirical evidence regarding these relationships. Section 5 summarizes our conclusions.

2. A Simple Open-Economy Model

The theoretical model combines elements of the framework utilized by Benavie (1983) and Daniels (1997) and the model developed in Daniels and VanHoose (2006). There are numerous atomistic firms, indexed i , distributed uniformly along a unit interval. In a portion, Ω , of firms, nominal wages are set in advance of labor-market clearing. In the portion of firms, $1-\Omega$, that do not utilize such contracts, spot labor markets determine nominal wages. In a closed-economy version of this type of model, Duca and VanHoose (2001) have shown that if risk-neutral firms and risk-averse workers face common aggregate shocks and diverse firm-specific disturbances, the contract share of firms Ω typically lies between zero and unity but rises as the volatility of aggregate shocks increases relative to the variability of firm-specific disturbances. To focus on the issues at hand, we treat Ω as an exogenous parameter and thereby abstract from considerations of shocks that can affect the share of firms with nominal wage contracts.

The output produced by a given firm i is given by

$$(1) \quad y_i = \alpha l_i,$$

where y_i is the log of output and l_i is the log of employment at firm i . The demand for the output of a domestic firm in sector i as a share of aggregate domestic output is

$$(2) \quad y_i - y = -\varepsilon(p_i - p),$$

where $y \equiv \int_0^1 y_i di$ is the log of aggregate domestic output, $p \equiv \int_0^1 p_i di$ is the log of the aggregate domestic price level, and $\varepsilon > 1$ is the elasticity of demand for the output of firms in sector i of the domestic country.

The domestic nation's income-expenditure equilibrium condition (for a derivation of this Cobb-Douglas approximation, see, for instance, Canzoneri and Henderson, 1991, or Bryson, *et al.*, 1993) is given by

$$(3) \quad y = \eta(p^* + s - p) + (1 - \beta)y + \beta y^* - \delta[r - (p_{+1}^e - p)];$$

where the average propensity to import, β , is a fraction; η is the elasticity of desired spending with respect to the real exchange rate; p^* is the log of the aggregate foreign price level; s is the log of the domestic currency price of foreign currency; y^* is the log of aggregate foreign output; δ is the semi-elasticity of domestic spending with respect to the domestic real interest rate; r is the domestic nominal interest rate, and p_{+1}^e is the current expected value of the log of the price level in the next period.

Domestic money market equilibrium is given by

$$(4) \quad m - p = \sigma y - \gamma r - \xi(r^* + s_{+1}^e - s),$$

where m is the log of the money stock, r^* is the foreign nominal interest rate, s is the log of the nominal exchange rate measured in units of domestic currency per unit of foreign currency, and s_{+1}^e is the current expected value of the log of the exchange rate in the following period. Including (4) would permit a thorough-going analysis of the implications of this model for equilibrium inflation in a setting in which the nominal money stock is an instrument of monetary policy. In a setting in which the instrument of monetary policy is the interest rate, (4) would play a role in determining the resulting endogenous quantity of money.

The balance-of-payments equilibrium condition is²

$$(5) \quad (1 + \eta)(p^* + s - p) - \mu y + \theta \kappa r - \theta \psi (r^* + s_{+1}^e - s) + \varphi y^* = 0,$$

where μ , θ , κ , ψ , and φ are nonnegative structural parameters. Note that if $\kappa = \psi$ and $\mu = \varphi$, then domestic and foreign bonds are perfect substitutes. If additionally the limiting case holds in which $\theta \rightarrow \infty$, then there is also complete capital mobility, and the uncovered interest parity condition is satisfied; that is, $r = r^* + s_{+1}^e - s$. More generally, a higher value of θ indicates an increase in the degree of capital mobility irrespective of the substitutability of domestic and foreign bonds, as long as $\kappa > 0$ and $\psi > 0$.

Specifying analogous structural relationships for a foreign nation would yield a two-country framework in which y^* , p^* , and r^* would be endogenous variables, but here we assume the output and prices abroad are exogenously determined. Henceforth, the foreign money stock, foreign price level, and foreign output are normalized at unity, so that p^* and y^* equal zero, and r^* is assumed equal to ρ , a constant world interest rate.

Using (5), (3), (2), and (1) in the profit function, $P_i Y_i - W_i L_i$, yields the labor demand function for a firm i (with the intercept suppressed because it plays no role in our subsequent analysis):

$$(6) \quad l_i^d = \frac{-\beta\varepsilon\omega(w_i - p) - \Theta p + \delta(1 + \eta + \theta\psi)p_{+1}^e + \eta\theta\psi(\rho + s_{+1}^e) - Ar}{\beta(\alpha + \varepsilon\omega - \alpha\varepsilon\omega)},$$

where w_i is the log of the nominal wage for the firm, $\omega \equiv 1 + \eta(1 - \mu) + \theta\psi$,

$\Theta \equiv \delta(1 + \eta + \theta\psi) + \eta\theta\psi$, and $A \equiv \delta(1 + \eta + \theta\psi) + \eta\theta\kappa$. Workers can consume domestic and foreign goods, so labor supply to firms depends on the real wage computed in terms of the overall price workers pay for a basket of both domestic and foreign goods:

$$(7) \quad l_i^s = \lambda[w_i - (1 - \beta)p - \beta s],$$

where $\lambda > 0$. Thus, for firms with or without nominal wage contracts, the full-information, market-clearing wage satisfies (6) and (7) simultaneously and equals

$$(8) \quad \hat{w}_i = \frac{[\beta(1 - \beta)\lambda(\alpha + \varepsilon\omega - \alpha\varepsilon\omega) + (\beta\varepsilon\omega - \Theta)]p + \delta(1 + \eta + \theta\psi)p_{+1}^e + \beta^2\lambda(\alpha + \varepsilon\omega - \alpha\varepsilon\omega)s + \eta\theta\psi(\rho + s_{+1}^e) - Ar}{\beta[\lambda(\alpha + \varepsilon\omega - \alpha\varepsilon\omega) + \varepsilon\omega]}.$$

Substitution of (8) into either (6) or (7) and the result into (1) yields output of a noncontract firm with market-clearing (*mc*) wages:

$$(9) \quad y_i^{mc} = \frac{\alpha\{[1 - \lambda(1 - \beta)]\beta\varepsilon\omega - \Theta\}p + \lambda\alpha\delta(1 + \eta + \theta\psi)p_{+1}^e + \beta^2\lambda\alpha(\alpha + \varepsilon\omega - \alpha\varepsilon\omega)s + \lambda\alpha\eta\theta\psi(\rho + s_{+1}^e) - \lambda\alpha\Lambda r}{\beta[\lambda(\alpha + \varepsilon\omega - \alpha\varepsilon\omega) + \varepsilon\omega]}.$$

Thus, the output of firms with market-determined nominal wages naturally depends on the current price level, anticipated exchange rate, and interest rate and on the anticipated future price level and exchange rate.

For the fraction, Ω , of firms with nominal wage contracts, if the contract wage is equal to the expected value of the market clearing wage, substituting the expectation of (8) into (6) and the result in (1) yields output of a firm with wage contracts, given by

$$(10) \quad y_i^c = \frac{(\beta\varepsilon\omega - \Theta)[\lambda\Gamma + \varepsilon\omega]p - \alpha\beta\varepsilon[\beta(1 - \beta)\lambda\Gamma + (\beta\varepsilon\omega - \Theta)]p^e + \alpha\beta\delta\{\lambda\Gamma + \varepsilon[\omega - (1 + \eta + \theta\psi)]\}p_{+1}^e}{\beta^2\Gamma[\lambda\Gamma + \varepsilon\omega]} + \frac{\{\alpha\beta\eta\theta\psi[\lambda\Gamma + \varepsilon\omega] - \alpha\beta\varepsilon\eta\theta\psi\}(\rho + s_{+1}^e) - \lambda\alpha\beta^2\varepsilon\Gamma s^e - \alpha\beta\Lambda\lambda[\lambda\Gamma + \varepsilon\omega]r - \alpha\beta\varepsilon\Lambda r^e}{\beta^2\Gamma[\lambda\Gamma(\alpha + \varepsilon\omega - \alpha\varepsilon\omega) + \varepsilon\omega]},$$

where $\Gamma \equiv (\alpha + \varepsilon\omega - \alpha\varepsilon\omega)$ and where p^e and s^e are the expectations of the current price level and exchange rate held by wage setters at the beginning of the current period based on prior information. Of course, these latter expectations play key roles in determining the contract nominal wage rate established at the outset of the period and hence influence equilibrium employment and output levels of firms utilizing wage contracts.

3. Relating Trade Openness and Capital Mobility to the Sacrifice Ratio

To explore the separate direct and interactive effects of trade openness and capital mobility on the sacrifice ratio, we note first that since firms behave identically, $y_i^c = y^c$ for all $i \in [0, \Omega]$, and $y_i^{mc} = y^{mc}$ for all $i \in (\Omega, 1]$. It follows that $y = (1 - \Omega)y^{mc} + \Omega y^c$, so that responsiveness of aggregate output to a change in the domestic price level is

given by $\frac{\partial y}{\partial p} = (1 - \Omega) \frac{\partial y^{mc}}{\partial p} + \Omega \frac{\partial y^c}{\partial p}$. Hence, the aggregate sacrifice ratio is the weighted average of the sacrifice ratio applicable to the portion of firms with spot-market-determined wages and the portion utilizing nominal wage contracts.

From (9) and (10), the separate effects of an increase in the price level on output for firms with and without nominal wage contracts are given by

$$(11) \quad \frac{\partial y^{mc}}{\partial p} = \frac{\alpha \{ [1 - \lambda(1 - \beta)] \beta \varepsilon \omega - \Theta \}}{\beta [\lambda(\alpha + \varepsilon \omega - \alpha \varepsilon \omega) + \varepsilon \omega]},$$

which is more likely to be positive if ε is significantly greater than unity, so that product markets are highly competitive, and if λ is relatively small, so that labor supply is relatively inelastic, and

$$(12) \quad \frac{\partial y^c}{\partial p} = \frac{\beta \varepsilon \omega - \Theta}{\alpha \beta (\alpha + \varepsilon \omega - \alpha \varepsilon \omega)},$$

which is also more likely to be positive if ε is significantly greater than unity, so that there is a relatively significant degree of competition in product markets.

It is straightforward to show that $\left(\frac{\partial y^{mc}}{\partial p} \right) > 0$ and that $\left(\frac{\partial y^c}{\partial p} \right) > 0$. As in Daniels and

VanHoose (2006), greater trade openness causes desired spending on domestic products to be responsive to changes in domestic income, which in turn causes profit-maximizing prices of firms in both labor-market-clearing and wage-contracting sectors to be less sensitive to a variation in aggregate domestic output. As a consequence, the aggregate price level is less responsive to a change in aggregate output, implying conversely that there is an increased sensitivity of output to a change in the price level. Together, these results imply that an increase in the average propensity to import

makes desired expenditures on domestic output less sensitive to changes in domestic income, so that each firm's profit-maximizing price is less responsive to a change in aggregate domestic output. Thus, greater trade openness unambiguously boosts the aggregate sacrifice ratio.

The effects of increased capital mobility in this model are less clear-cut. For firms at which contracts set nominal wages in advance of product-market clearing, cumbersome computations verify that, for $\psi > 0$, the sign of $\frac{\left(\frac{\partial y^c}{\partial p}\right)}{\partial \theta}$ hinges in large part on the interest-rate sensitivity of aggregate demand relative to the real-exchange-rate responsiveness of domestic demand. This conclusion is analogous to that derived by Loungani, Razin, and Yuen (2001) in the context of a combined flexible-price/sticky-price framework. As in their model, in the portion of the economy that is not directly constrained by nominal rigidities, there is greater scope for interest-rate and real-exchange-rate adjustments that in turn feed back to induce price and wage adjustments at these firms. In contrast to the economy-wide sticky-price settings considered by Razin and Yuen (2002) and Razin and Loungani (2005), which give rise to an unambiguously positive value for $\frac{\left(\frac{\partial y^c}{\partial p}\right)}{\partial \theta}$, wage and price adjustments at firms with market-determined wages spill over to influence prices at firms utilizing nominal wage contracts. As a consequence, the relative sensitivities of aggregate demand to interest-rate and real-exchange-rate variations are crucial determinants of the responsiveness of output to the price level at firms with market-clearing wages. It can be shown that, in accord with the conclusions of Loungani *et al.*, greater capital mobility boosts the sacrifice ratio—that is, $\frac{\left(\frac{\partial y^{mc}}{\partial p}\right)}{\partial \theta} > 0$ —for parameter configurations ψ and δ that are sufficiently large, so that there is a relatively high interest sensitivity of domestic and

foreign asset demands and a relatively large interest responsiveness of desired domestic expenditures, and in which η is sufficiently small, so that desired domestic spending is relatively unresponsive to variations in the real exchange rate.

For the portion of the economy comprised of firms with market-determined wages, the sign of $\frac{\left(\frac{\partial y^{mc}}{\partial p}\right)}{\partial \theta}$ is highly ambiguous. At firms with market-clearing wages, adjustments of product prices and nominal wages are restrained only to the extent that spillovers are created by the failure of wages to adjust at firms with nominal wage contracts. Although interactions among the relative magnitudes of λ, ψ, δ , and η determine the sign of $\frac{\left(\frac{\partial y^{mc}}{\partial p}\right)}{\partial \theta}$ in this case as well, the interplay between fully adjusting prices and wages—again, subject to spillovers from firms with nominal wage contracts—yields complicated effects of prices on output that are difficult to disentangle.

The upshot of this analysis is that to the extent that our model yields a prediction about how greater capital mobility is likely to influence the sacrifice ratio, this prediction depends crucially on the labor supply elasticity, the interest-rate sensitivities of domestic and foreign asset demands, and the interest-rate responsiveness of desired domestic expenditures. Under certain parameter configurations we can obtain a definite prediction that increased capital mobility is likely to generate a rise in the sacrifice ratio in nations in which nominal rigidities are an important feature. In nations experiencing nominal rigidities but contrary parameter configurations, however, the opposite effect could emerge. In countries in which significant portions of firms charge market-determined product prices and pay market-determined wages, the model yields no definite theoretical predictions regarding the effects of greater capital mobility on the sacrifice ratio.

The model does, however, yield more straightforward implications regarding the effects that an increased degree of capital mobility has on the impact of trade openness

on the sacrifice ratio—that is, the sign of $\frac{\partial^2 \left(\frac{\partial y^{mc}}{\partial p} \right)}{\partial \beta \partial \theta}$. For both firms with and without

nominal wage contracts, greater capital mobility enhances the positive effect of trade openness on the sacrifice ratio if ψ and δ are sufficiently large and η is sufficiently small. Thus, a reinforcing effect of capital mobility on the sacrifice-ratio impact of trade openness is also more likely if there is a relatively high interest sensitivity of domestic and foreign asset demands and a relatively large interest responsiveness of desired domestic spending.

Greater trade openness does nothing to clear up the theoretical ambiguities of the effects of greater capital mobility on the sacrifice ratio. Consequently, the theoretical model offers no clear-cut predictions regarding whether or not increased trade openness may or may not reinforce the impact of greater capital mobility on the sacrifice ratio.

4. Empirical Implications and Evidence

The forgoing discussion yields three empirical implications:

- i) taking into account the effect of central bank independence, increased trade openness makes output more price-sensitive and consequently raises the sacrifice ratio;
- ii) higher capital mobility generally has uncertain affects on the sacrifice ratio, but in nations in which the use of nominal wage contracts is more widespread, greater capital mobility is more likely to boost the sacrifice ratio if domestic spending is relatively responsive to interest-rate changes but relatively unresponsive to real-exchange-rate variations; and

- iii) if domestic expenditures are relatively sensitive to interest-rate variations but relatively insensitive to changes in real exchange rates, higher capital mobility is likely to reinforce the positive effect of increased trade openness on the sacrifice ratio.

Below, we do not attempt to measure relative responsiveness of aggregate spending to interest-rate and exchange-rate variations across countries. We do, however, utilize measures of trade openness, capital mobility, central bank independence, and wage duration in an attempt to evaluate the independent and interactive effects of these variables on the sacrifice ratio in cross-country data.

4.1 Data

We employ the data made available by Temple (2002) and Daniels *et al.* (2005), taken from Ball (1994), to test our hypotheses regarding the sacrifice ratio. This data set includes estimates of the sacrifice ratio (SAC) for 58 disinflationary periods occurring in 16 moderate inflation OECD economies from 1960 through the 1980s, initial inflation preceding the disinflationary episode, the change in inflation during the disinflationary period ($\text{Inflation}\Delta$), the length of the deflationary period (Length), and a measure of wage contract duration (Wdur). We augment this data with several other variables. First, we add the degree of central bank independence (CBI), taken from Franzese (2002), which is a weighted average of legal independence, a characterization of independence based on answers to a survey completed by individuals at central banks (Cukierman, 1992), economic independence, political independence (Grilli, *et al.*, 1991), and Bade and Parkin's (1982) index of central bank independence. Next we add a measure of trade openness (Trade) which is the average of the sum of imports and exports as a percentage of GDP over the sample period, and a measure of capital mobility (Capital) which is the average of the sum of total capital inflows and outflows as a percentage of GDP. Data on trade flows and capital flows are taken from the

International Monetary Fund's *International Financial Statistics*. Table 1 contains descriptive statistics on the sample data.

4.2 Trade Openness and the Sacrifice Ratio

Daniels *et al.* (2005) examine the impact of trade openness on the sacrifice ratio using the average of imports as a percentage of GDP. They show the importance of accounting for the interaction of CBI and openness and suggest testing for outliers in the data. We employ the same measures for the sacrifice ratio, but we measure trade openness as the average of the sum of imports and exports as a percentage of GDP. Following Daniels *et al.*, we test for outliers using the DFITS test, Cook's distance test, and Welsch's distance test, and our results similarly identify Germany's 1973-1978 disinflation episode as an outlier. We drop this single observation from all of our regression models.

The results in columns 1 and 2 of Table 2 reaffirm Daniels *et al.*'s conclusion that the coefficient of trade openness is insignificant (column 1) unless its interaction with central bank independence is included. Column 2 includes this interaction, with the results that the coefficient on trade openness is positive and statistically significant, while the coefficient of the interaction term is negative and significant. Hence, we re-attain the Daniels *et al.* result that trade openness and the sacrifice ratio are positively related and greater CBI reduces the effect of trade openness on the sacrifice ratio.

4.2 Trade Openness, Capital Mobility,, and the Sacrifice Ratio

Aizenman and Noy (2004) examine the correlation among financial and trade openness, measured as the sum of capital inflows and outflows as a percentage of GDP and as the sum of imports and exports as a percentage of GDP, respectively. They show that there is a linear two-way feedback relationship among the two openness variables. This simultaneous correlation between the two openness variables

is, of course, problematic in our empirical study making it difficult if not impossible to isolate the individual effects of trade openness and capital mobility.³ This problem is compounded by the fact that some of our variables, CBI and wage duration in particular, have limited variability within our data set. One method of dealing with this problem would be to expand the sample, not only increasing our degrees of freedom but also the variation of key variables. However, combining estimates of the sacrifice ratio, central bank independence and (especially) wage duration is problematic and limits our ability to expand the data, resulting in less than 60 usable observations. Hence, to examine the relationship between capital mobility and the sacrifice ratio, we reduce colinearity among the variables by dropping the interaction term between trade openness and central bank independence in the remaining columns of Table 2 and in Columns 3, 4, and 5 of Table 2 we replace trade openness with capital mobility as the single measure of international openness. Furthermore, we examine the interaction of capital mobility with CBI and wage duration separately.⁴ In column 3, the effect of capital mobility on the sacrifice ratio is positive but statistically insignificant. In column 4, we find that accounting for an interaction between capital mobility and central bank independence leads to the implication of a positive (statistically significant at the 10 percent level) effect of greater capital mobility on the sacrifice ratio. As with the trade openness measure of international openness, however, the impact of capital mobility on the sacrifice ratio is significantly reduced by increased central bank independence.

In comparing columns 3 and 4 to columns 1 and 2, it is tempting to conclude that in light of the relatively high bilateral correlation between trade openness and capital mobility, the empirical results suggest that both international openness measures are essentially substitutable. Recall, however, that the theoretical model suggests a positive interaction between the degree of wage stickiness and the sacrifice-ratio effect of greater capital mobility. Column 5 includes an interaction between our measures of these two variables. Doing so results in a statistically insignificant estimated effect of

capital mobility on the sacrifice ratio but a positive (statistically significant at the 10 percent level) interactive effect of wage duration and capital mobility. Thus, consistent with the theory, the degree of wage stickiness plays a key role in conditioning capital mobility's sacrifice-ratio impact.

The relatively high correlation between our trade openness and capital mobility measures suggests that including both as independent variables is a problematic exercise. Nevertheless, for the sake of completeness in examining the implications forthcoming from the data, in columns 6, 7, and 8 of Table 2 we include both international openness measures. The coefficient estimate for capital mobility is positive but statistically insignificant in column 6. When the interaction between capital mobility and wage duration is added in column 7, the direct effect of capital mobility on the sacrifice ratio remains statistically insignificant (p-value of 20 percent, two-tailed test). Consistent with theory, however, the effect of an interaction between capital mobility and wage duration is positive and significant, indicating that a greater degree of wage rigidity tends to bring about a positive effect of increased capital mobility on the sacrifice ratio. Nevertheless, in both of the models for which results are displayed in columns 6 and 7, tests of a joint significance of trade and capital mobility effects on the sacrifice ratio are insignificant.

Column 8 reports the results of adding an interaction term between trade openness and capital mobility. Neither the openness measures nor the interaction term are significant, nor are they jointly significant. Thus, the empirical results do not resolve the theoretical prediction indicating that greater capital mobility potentially could reinforce the sacrifice-ratio impact of increased trade openness.

What can we conclude from these results? First, consistent with earlier work by Daniels *et al.* (2005) and with the model developed in this paper, increased openness to international trade has a positive effect on the sacrifice ratio once the dampening effect of greater central bank independence (CBI) is taken into account. Second, consistent

with evidence offered by Razin and Loungani (2005), accounting for the conditioning effects of CBI implies that greater capital mobility also boosts the sacrifice ratio. Third, the finding that greater wage stickiness boosts the positive effect of greater capital mobility on the sacrifice ratio is consistent with the prediction of our theoretical model when aggregate spending is more sensitive to interest-rate variations than to exchange-rate variations. This finding highlights the importance of considering potential effects specific to increased capital mobility rather than considering the impact of “globalization” to be captured by trade openness alone. Fourth, the theoretical model suggests that increased openness to trade and greater capital mobility may have self-reinforcing positive effects on the sacrifice ratio, although the positive correlation between the two globalization measures complicates interpreting regression results in which both measures are taken to be independent variables. When we treat both measures of international openness as independent variables, we obtain a positive coefficient estimate on the interactive effect that the two have on the sacrifice ratio, but this estimate is statistically insignificant.

Taken together, the first three conclusions provide support for concluding from cross-country data that increased trade openness and greater capital mobility do indeed independently tend to boost the sacrifice ratio. Thus, our analysis supports the conclusion that globalization, whether through more openness to trade or greater openness to capital flows, contributes to a shallower Phillips curve. Although our theoretical framework indicates that there is also a potential for interactive effects of the two globalization measures on the sacrifice ratio, we do not find evidence of statistically significant interacting impacts of increased trade openness and greater capital mobility.

5. Conclusion

This paper has developed and empirically evaluated implications of an open-economy framework exploring the separate impacts of, and interactions among trade openness and capital mobility as factors affecting the sacrifice ratio. Consistent with our theoretical model, we find evidence in cross-country data of separate effects of increased trade openness and greater capital mobility influence the sacrifice ratio. Once the conditioning effect of central bank independence is taken into account, we find that increases in both measures of international openness result in a higher sacrifice ratio. We also find evidence that greater wage duration enhances the positive sacrifice-ratio effect of more mobile capital, which is consistent with our theory's implication that the impact of greater capital mobility is positively related to the degree of wage stickiness in a nation's economy. Although our model suggests the potential for greater capital mobility to enhance the sacrifice-ratio impact of increased trade openness, the empirical results do not necessarily provide support for this prediction.

Overall, our analysis of cross-country data supports the conclusion that the forces of globalization—whether manifested as from increased openness to international trade or greater mobility of capital—tend to raise the sacrifice ratio. In our view, future work examining the impact of globalization on the sacrifice ratio should focus on country-specific data [see, for instance, early work along these lines in Ball (2006) and Sbordone (2007)]. It remains to be seen to what extent increased trade openness and greater capital mobility affect the inflation sensitivity of output and the slope of the Phillips curve within individual nations.

Glossary

SAC \equiv Sacrifice Ratio¹

CBI \equiv Central Bank Independence, index of central bank independence²

Inflation \equiv Change in GDP deflator¹

Inflation Δ \equiv Drop in the rate of inflation during the given period¹

Length \equiv Length of disinflationary period in years¹

Wdur \equiv wage contract duration¹

Trade \equiv ratio of the sum of imports and exports to nominal GDP³

Capital \equiv sum of capital inflows and capital outflows to nominal GDP³

¹ Temple (2002), Daniels *et al.* (2005), ² Franzese (2002), ³ Calculated from the *International Financial Statistics*

FOOTNOTES

¹ There can be crucial differences between the ultimate policy implications of sticky-price versus sticky-wage models, however, because in the former models a portion of firms in the economy hold prices fixed, typically in light of menu costs, even after monetary policymakers have engaged in policy actions, whereas in the latter models monetary policy actions take place before prices are set, and firms optimally choose not to adjust prices fully in light of wage rigidities.

² The derivation of this condition mirrors Benavie (1983). From (3) the net trade balance is $\eta(p^* + s - p) - \beta y + \beta y^*$. If the flow demand for domestic bonds is given by $b^d = \varphi y^* + \theta\chi r - \theta\varpi(r^* + s_{+1}^e - s) + p^* + s$, and if the flow demand for foreign bonds is given by $b^f = \mu y - \theta\vartheta r + \theta\nu(r^* + s_{+1}^e - s) + p$, then the net domestic capital inflow is defined as $b^d - b^f = (p^* + s - p) - \mu y + \theta\kappa r - \theta\psi(r^* + s_{+1}^e - s) + \varphi y^*$, where $\kappa \equiv \varpi + \nu$ and $\psi \equiv \chi + \vartheta$.

Adding the expression for the trade balance to the net capital inflow yields (5).

³ Aizenman and Noy estimate an 87 percent linear feedback between trade openness and financial openness. The simple bilateral correlation between trade openness and capital mobility in our data is 79 percent.

⁴ One way to deal with the colinearity in our model is to test the joint significance of the related variables. We do so in a model that includes trade and capital as well as their interaction with CBI. In this model, trade and capital are jointly significant with a p-value of 3 percent. We also combine models (4) and (5) in Table 2 and test the joint significance of capital, capital*Wdur, and capital*CBI. The p-value of the test of joint significance (two-tailed test) is 17 percent.
