Abstract

Stress-induced reinstatement of cocaine seeking requires corticotropin releasing factor (CRF) actions in the ventral tegmental area (VTA). However, the mechanisms through which CRF regulates VTA function to promote cocaine use are not fully understood. Here we examined the role of GABAergic neurotransmission in the VTA mediated by GABA-A or GABA-B receptors in the reinstatement of extinguished cocaine seeking by a stressor, uncontrollable intermittent footshock, or bilateral intra-VTA administration of CRF. Rats underwent repeated daily cocaine self-administration (1.0 mg/kg/ing; 14 × 6 h/day) and extinction and were tested for reinstatement in response to footshock (0.5 mA, 0.5” duration, average every 40 s; range 10–70 s) or intra-VTA CRF delivery (500 ng/side) following intra-VTA pretreatment with the GABA-A antagonist, bicuculline, the GABA-B antagonist, 2-hydroxysaclofen or vehicle. Intra-VTA bicuculline (1, 10 or 20 ng/side) failed to block footshock- or CRF-induced cocaine seeking at either dose tested. By contrast, 2-hydroxysaclofen (0.2 or 2 μg/side) prevented reinstatement by both footshock and intra-VTA CRF at a concentration that failed to attenuate food-reinforced lever pressing (45 mg sucrose-sweetened pellets; FR4 schedule) in a separate group of rats. These data suggest that GABA-B receptor-dependent CRF actions in the VTA mediate stress-induced cocaine seeking and that GABA-B receptor antagonists may have utility for the management of stress-induced relapse in cocaine addicts.

1. Introduction

Understanding the mechanisms that contribute to relapse to drug use in cocaine addicts is critical for the development of new and
more effective treatment approaches for managing addiction. In rats, relapse can be studied using reinstatement models in which the ability of a stimulus to re-establish or reinstate cocaine seeking behavior in rats or mice following extinction is used as an indicator of its likelihood to promote relapse to use in human addicts (Mantsch et al., 2015). Many of the same stimuli that contribute to drug use in humans (stress, drug-associated cues, drug re-exposure), reinstate cocaine seeking following self-administration (SA) and extinction in rats.

Among the triggers for relapse, stress is particularly problematic due to its unpredictable and often uncontrollable nature. Reports from cocaine users that relapse is frequently related to the onset of stressful life events are supported by laboratory findings demonstrating that personalized scripts that relay stress-related imagery can precipitate craving in cocaine-dependent individuals (Sinha et al., 1999). In rats, it has been reported that a number of stressors can reinstate extinguished cocaine seeking following intravenous self-administration (see Mantsch et al., 2015 for review). However, most studies investigating stress-induced relapse in rats have used electric footshock delivered through the grid floor of the operant conditioning chambers as the reinstating stressor. Notably, we have previously reported that, like stress imagery in human addicts (Fox et al., 2005), the ability of footshock to reinstate cocaine seeking in rats increases according to the amount of prior drug intake (Mantsch et al., 2008).

Several studies have demonstrated that stress-induced reinstatement of cocaine seeking requires corticotropin-releasing factor (CRF) actions in the ventral tegmental area (VTA; Wang et al., 2005, Wang et al., 2007, Blacktop et al., 2011, Chen et al., 2014 and Vranjkovic et al., 2014) and that intra-VTA CRF administration is sufficient to reinstate cocaine seeking following SA and extinction in rats (Wang et al., 2005 and Blacktop et al., 2011). However, the downstream processes in the VTA through which CRF promotes drug use are unclear. Mechanistic studies have focused on CRF regulation of glutamatergic neurotransmission in the VTA (Wise and Morales, 2010). In the VTA, CRF has been reported to increase glutamate release as measured by both in vivo microdialysis (Wang et al., 2005) and spontaneous EPSCs in slice preparations (Hahn et al., 2009 and Williams et al., 2014), as well as post-synaptic excitability through increases in AMPA:NMDA receptor ratios (Ungless...
et al., 2003 and Hahn et al., 2009). Moreover, intra-VTA perfusion with kynurenic acid, which has a pharmacological profile that includes AMPA and NMDA receptor antagonism, prevents reinstatement in response to either footshock or intra-VTA CRF (Wang et al., 2005).

However, the actions of stress and CRF in the VTA are complex and appear to also include, under some circumstances, inhibition of neuronal activity (Ungless et al., 2004, Wanat et al., 2013 and Twining et al., 2015) or terminal neurotransmitter release (Williams et al., 2014). The VTA receives dense GABAergic inputs from a number of regions, including the nucleus accumbens (Yim and Mogenson, 1980, Xia et al., 2011 and Bocklisch et al., 2013) and bed nucleus of the stria terminalis (Kudo et al., 2012), both of which have been implicated in stress-induced cocaine seeking in rats (Erb and Stewart, 1999, McFarland et al., 2004 and Vranjkovic et al., 2014). Additionally, the VTA contains GABAergic interneurons that regulate efferent neuronal projections from the region (Steffensen et al., 1998 and Cruz et al., 2004) and dense GABAergic innervation from the rostromedial tegmental nucleus (i.e., tail of the VTA; Jhou et al., 2009, Matsui and Williams, 2011 and Barrot et al., 2012). It has also been reported that CRF promotes GABAergic neurotransmission within the VTA. For example, CRF application to the VTA in ex vivo slice preparations promotes GABA-B regulation of G protein-coupled inwardly-rectifying potassium (GIRK) channels on dopamine cells (Beckstead et al., 2009). Despite these findings, the effects of GABA receptor antagonism in the VTA on stress-induced reinstatement have not been reported.

In the present study we investigate the potential contribution of GABA_A and GABA_B receptors in the VTA to the reinstatement of extinguished cocaine seeking in response to footshock or delivery of CRF into the VTA following self-administration. Rats with a history of daily self-administration that results in robust shock and intra-VTA CRF-induced reinstatement following extinction (14 × 6 h/day; 1 mg/kg/inf) received intra-VTA injections of the GABA_A receptor antagonist, bicuculline, or the GABA_B receptor antagonist, 2-hydroxysaclofen, prior to reinstatement testing. Notably, in contrast to previous work targeting VTA GABA receptors which used a cocktail of receptor agonists (baclofen/muscimol; McFarland et al., 2004), the present study uses receptor selective antagonists, thereby permitting
1) assessment of the contribution of GABA_A vs. GABA_B receptors and 2) the regulation of cocaine seeking through GABAergic signaling that is engaged by CRF and/or during stress.

2. Methods

2.1. Subjects

Adult male Sprague–Dawley rats (Harlan Laboratories, St. Louis, MO) were housed individually under a 12 h/12 h reversed light/dark cycle (lights on at 7:00 PM) in a temperature and humidity controlled AAALAC-accredited animal facility. All procedures were approved by the Marquette University IACUC and carried out in accordance with the NIH Guide for the Care and Use of Laboratory Animals.

2.2. Catheter and cannula implantation

For the reinstatement studies, rats were implanted with chronic indwelling jugular catheters under ketamine HCl (100 mg/kg, ip) and xylazine (2 mg/kg, ip) anesthesia and with bilateral 2.1-cm 23 gauge guide cannulae aimed at the VTA for intracranial injections as previously described (Blacktop et al., 2011 and Vranjkovic et al., 2014). The tips of the guide cannulae were aimed 0.5 mm above the target injection site (the posterior VTA) using the following coordinates determined from Paxinos and Watson (2007): 12° angle away from midline; A/P = −5.6 mm from bregma; M/L ± 2.2 mm from midline; and D/V = −6.7 mm from the skull surface. Placements for cannula targeting the VTA for rats from each of the experiments are depicted in Fig. 1.

![Fig. 1. Intracranial injection sites. Panels represent atlas diagrams (coronal sections −5.6, −5.8 and −6.1 mm relative to Bregma; Paxinos and Watson, 2007)](image-url)
depicting injection sites from rats included in experiments in which effects of VTA injections of 1 ng/side (closed circles), 10 ng/side (open circles), or 20 ng/side (open triangles) bicuculline on CRF- and shock-induced cocaine seeking were tested (left); rats included in experiments in which effects of VTA injections of 0.2 μg/side (closed circles) or 2 μg/side (open squares) 2-hydroxysaclofen on CRF- and shock-induced cocaine seeking were tested and rats with injections outside of the VTA used as anatomical controls (center; closed triangles); and rats included in the experiments testing for effects on food-reinforced lever pressing (right; closed circles).

2.3. Drugs

Cocaine HCl was provided by the National Institute on Drug Abuse through the Drug Supply Program. CRF was purchased from Sigma–Aldrich and was administered at a concentration of 500 ng/side (Blacktop et al., 2011) dissolved in artificial cerebral spinal fluid (aCSF; 0.25 μl/side). The GABA_A receptor antagonist (−)-bicuculline methiodide was purchased from Tocris Bioscience and was administered at doses of 1, 10 and 20 ng/side (0.002 and 0.02 and 0.04 nmol/side) dissolved in aCSF (0.25 μl/side). The doses used were selected based on prior reports assessing VTA effects (Sandner et al., 1996, Trojniar and Klejbor, 1999, Laviolette and van der Kooy, 2001, Grubb et al., 2002, Echo et al., 2002 and Lavezzi et al., 2015). The occurrence of seizures prevented testing for effects of higher doses. The GABA_B receptor antagonist 2-hydroxysaclofen was also purchased from Tocris Bioscience and was administered at doses of 0.2 and 2 μg/side (0.75 and 7.5 nmol/side) dissolved in aCSF (0.25 μl/side). The doses used were also selected based on prior reports assessing VTA effects (Xi and Stein, 1999, Echo et al., 2002, Ackerman et al., 2003 and Miner et al., 2010).

2.4. Cocaine self-administration/extinction

After recovery from surgery, rats were trained to self-administer cocaine (1.0 mg/kg/inf, iv) by pressing a lever under a fixed ratio 1 schedule during daily 2-h sessions, within which the active (i.e., front) lever was extended into the chamber and the corresponding stimulus light was illuminated. Pressing the lever resulted in an iv infusion of cocaine solution (200 μl over 5 s) followed by a 25-s time-out period during which the stimulus light was extinguished but the lever remained extended. Responding on a second, inactive (i.e., back) lever was recorded but had no programmed consequences. Response requirements were gradually increased until rats displayed stable...
responding (within 10% of the mean over 3 consecutive sessions) under an FR4 schedule at which time they were allowed to self-administer cocaine six hours daily for 14 consecutive days. We have previously found that robust reinstatement of cocaine seeking in response to either footshock or intra-VTA CRF is only observed when rats are tested after self-administration under these “long-access” conditions (Mantsch et al., 2008 and Blacktop et al., 2011). After the 14-day self-administration test period rats underwent extinction during ten consecutive 2-h sessions within which the cocaine solution was replaced by saline. As was the case during self-administration, the drug lever stimulus light was illuminated during the extinction session except during the post-infusion “time-out” period. Once rats displayed less than 20 responses/session over two consecutive sessions under extinction conditions, reinstatement testing was initiated.

2.5. Reinstatement testing

After extinction, rats were tested for the effects of intra-VTA pretreatment with either bicuculline (GABAA antagonist) or 2-hydroxysaclofen (GABAB antagonist) on reinstatement in response to electric footshock or bilateral intra-VTA CRF injections. Separate groups of rats were tested for the effects of 1 ng, 10 or 20 ng/side bicuculline or 0.2 or 2 μg/side 2-hydroxysaclofen. Each rat was tested for reinstatement in response to shock and intra-VTA CRF following intra-VTA vehicle and drug pretreatment (four reinstatement tests total). The two-hour reinstatement sessions were otherwise identical to the extinction sessions (i.e., the drug lever stimulus light was illuminated except during the post-infusion “time-out” period). Consecutive reinstatement sessions were always separated by additional extinction training and rats were required to display less than 20 cocaine lever responses during an intervening extinction session in order to be tested again for reinstatement. The sequence of reinstatement testing (shock and CRF) was counterbalanced across rats such that some rats were tested for effects on shock-induced reinstatement first, while others were tested for CRF-induced reinstatement first. All microinfusions were delivered in a volume of 0.25 μl/side over a 1-min period with an additional 1-min period to allow for drug diffusion, ten minutes prior to the reinstatement session. In addition to testing for the effects of GABA receptor

Neuropharmacology, Vol 102 (March 2016): pg. 197-206. DOI. This article is © Elsevier and permission has been granted for this version to appear in e-Publications@Marquette. antagonists on shock- and CRF-induced cocaine seeking, the effects of intra-VTA administration of bicuculline and 2-hydroxysaclofen in the absence of shock or CRF were assessed in separate groups of rats.

2.6. Shock-induced reinstatement of cocaine seeking

To determine the contribution of VTA GABA_A and GABA_B receptors to stress-induced cocaine seeking, rats were tested for the ability of electric footshock, delivered though the stainless steel grid floors of the self-administration chambers, to reinstate cocaine seeking following pretreatment with bilateral antagonist drug injections into the VTA ten minutes prior to shock. During the 15-min footshock period, the houselight was illuminated and the levers were retracted and stimulus lights extinguished. Shocks (0.5 mA, 0.5” duration) were delivered an average of every 40 s (range 10–70 s). Immediately following the shock period, the houselight was extinguished and the active and inactive levers were extended into the chamber and the active lever stimulus light was illuminated (conditions identical to both self-administration and extinction). We have reported that these parameters produce robust footshock-induced reinstatement under the self-administration conditions used (Mantsch et al., 2008). Each rat was tested twice for shock-induced reinstatement in counter-balanced sequence: once following intra-VTA drug delivery and once following intra-VTA vehicle administration.

2.7. CRF-induced reinstatement of cocaine seeking

Rats were also tested for reinstatement in response to bilateral intra-VTA injections of CRF. Ten minutes after VTA administration of bicuculline, 2-hydroxysaclofen or vehicle, rats received bilateral injections with CRF (500 ng/side delivered a volume of 0.25 μl/side over a 1-min period ten minutes prior to reinstatement testing). Each rat was tested twice for CRF-induced reinstatement in counter-balanced sequence: once following intra-VTA drug delivery and once following intra-VTA vehicle administration. We have previously reported that this CRF concentration produces robust reinstatement under the self-administration conditions used (Blacktop et al., 2011). Moreover, CRF delivery via cannula placed into regions adjacent to the VTA failed to reinstate cocaine seeking (n = 5; extinction responses/2-
Session: 11.2 ± 1.59; CRF-induced responses/2-h session: 8.8 ± 1.39).

2.8. Testing for effects on food-reinforced lever pressing

In order to confirm that the effects of intra-VTA injections on reinstatement were not attributable to non-specific motor impairment, separate groups of rats were tested for effects on sucrose pellet-reinforced lever pressing. These rats were maintained at 90% of their free-feeding body weights and trained to self-administer 45 mg sucrose-sweetened food pellets (BioServ) by pressing a response lever under a FR4 schedule of reinforcement during 30-min sessions. Once stable response patterns were observed (responding within 10% of the mean over 3 sessions), rats were tested for the effects of intra-VTA delivery of 2-hydroxysaclofen, as described above, on responding.

2.9. Histological confirmation of injection sites

The accuracy of cannula implantation was confirmed postmortem in each rat after cardiac perfusion with 60-ml NaCl followed by 60-ml 2.5% buffered neutral formalin under sodium barbital anesthesia (55 mg/kg). Brains were removed and stored in 2.5% buffered formalin for at least one day. 200-μm sections were cut using a vibrotome, slide-mounted, and stained with cresyl violet for placement confirmation using a light microscope. Rats with injection sites outside of the VTA were excluded from the primary analysis and combined into a separate “missed placement” group for assessment of anatomical specificity of drug effects on shock-induced cocaine seeking.

2.10. Statistical analyses

The effects of each drug/dose combination on CRF and shock-induced reinstatement were analyzed separately using 2-way repeated measure ANOVA with reinstatement (responding during the reinstatement session vs. the preceding extinction session) and intra-VTA drug treatment (drug vs. vehicle) as factors. A similar analysis was used to assess effects on food-reinforced responding (2-way
repeated measures with reinforced lever pressing and drug treatment as factors). Analysis of drug effects alone consisted of comparison with the prior extinction session using paired t-tests. Statistical analyses were conducted using SPSS statistics software. For all analyses, statistical significance was defined as p < 0.05.

3. Results

3.1. Placements

The sites of injections for rats tested for the effects of intra-VTA drug injections and for anatomical control rats are depicted in Fig. 1.

3.2. SA and extinction

Cocaine self-administration and extinction in rats used for each experiment are shown in Table 1 and were comparable across groups. Moreover, the numbers of sessions required for acquisition of cocaine self-administration, total cocaine intake across all self-administration sessions and the numbers of sessions needed to reach the extinction criteria did not differ across groups (data not shown).

Table 1. Cocaine self-administration and extinction in each group of rats that underwent reinstatement testing. Data represent infusions/6-h session (±S.E.) on days 1 and 14 of self-administration and responses/2-h session (±S.E.) during the final extinction session prior to starting reinstatement testing in separate groups of rats tested for effects of intra-VTA bicuculline (1, 10, or 20 ng/side) or 2-hydroxysaclofen (0.2 or 2 μg/side) on shock and CRF-induced reinstatement.

3.3. Intra-VTA injections of 2-hydroxysaclofen or bicuculline do not reinstate cocaine seeking

Neither intra-VTA 2-hydroxysaclofen nor intra-VTA bicuculline injections induced cocaine-seeking behavior. Cocaine seeking following intra-VTA injections of bicuculline (10 or 20 ng/side; n = 4/dose) or 2-hydroxysaclofen (0.2 or 2 μg/side; n = 5/dose) is shown in Fig. 2. Separate 2-way ANOVAs failed to show overall increases in responding (i.e., reinstatement) relative to extinction, effects of intra-VTA drug dose or reinstatement × dose interactions.

![Fig. 2](image)

Fig. 2. Intra-VTA injections of bicuculline or 2-hydroxysaclofen do not induce cocaine seeking. Data represent responding (lever presses/2-h session ±S.E.) recorded during reinstatement testing following intra-VTA injections of vehicle and bicuculline (BIC; 10 or 20 ng/side; A) or 2-hydroxysaclofen (2-HS; 0.2 or 2 μg/side; B) and responding during the corresponding previous extinction (Ext) sessions.

3.4. Effects of intra-VTA bicuculline injections on shock- and intra-VTA CRF-induced reinstatement

Antagonism of GABA<sub>A</sub> receptors in the VTA failed to alter stress- or intra-VTA CRF-induced cocaine seeking. The effects of intra-VTA injections of three bicuculline concentrations (1 ng/side, 10 ng/side, and 20 ng/side) on shock-induced cocaine seeking were tested and are shown in Fig. 3. Consistent with other reports (e.g., Echo et al., 2002) we were unable to administer higher concentrations due to the emergence of seizures. Separate 2-way repeated measures (reinstatement × drug treatment) ANOVAs were conducted for each bicuculline dose. In all cases, shock-induced reinstatement was not
altered by intra-VTA bicuculline. At each bicuculline concentration, significant shock-induced reinstatement was observed (1 ng/side: \( F_{1,5} = 9.967, P < 0.05, n = 6 \); 10 ng/side: \( F_{1,4} = 42.631 \ P < 0.01, n = 5 \); 20 ng/side: \( F_{1,3} = 33.178 \ P = 0.01, n = 4 \)). However significant effects of VTA bicuculline administration or significant bicuculline × reinstatement interactions were not found.

![Fig. 3](image_url)

**Fig. 3.** Effects of intra-VTA bicuculline injections on stress-induced reinstatement. Data represent responding (lever presses/2-h session ±S.E.) recorded during reinstatement testing following electric footshock (0.5 mA, 0.5″ shocks delivered an average of every 40 s over a 15-min period) in rats pretreated with intra-VTA injections of vehicle or 1 ng/side (A), 10 ng/side (B), or 20 ng/side (C) concentrations of the GABA\(_A\) receptor antagonist, bicuculline (BIC), and responding during the previous extinction (Ext) session. Shock reinstated cocaine seeking regardless of whether rats were pretreated with vehicle or intra-VTA bicuculline (*P < 0.05 overall shock reinstatement effect vs. Ext but no effect of BIC or shock × BIC interaction).

The effects of intra-VTA injections of the three bicuculline concentrations (1 ng/side, 10 ng/side, and 20 ng/side) on cocaine seeking in response to bilateral intra-VTA CRF injections (500 ng/side) are shown in Fig. 4. Separate 2-way repeated measures (reinstatement × drug treatment) ANOVAs were conducted for each bicuculline concentration. As was the case with shock, CRF-induced reinstatement was not altered by intra-VTA bicuculline. At each bicuculline concentration, significant CRF-induced reinstatement was observed (1 ng/side: \( F_{1,5} = 35.698, P = 0.001, n = 6 \); 10 ng/side: \( F_{1,4} = 15.896, P < 0.05, n = 5 \); 20 ng/side: \( F_{1,3} = 271.75, P < 0.001, n = 4 \)). However significant effects of bicuculline administration or significant bicuculline × reinstatement interactions were not found.
Fig. 4. Effects of intra-VTA bicuculline injections on CRF-induced reinstatement. Data represent responding (lever presses/2-h session ±S.E.) recorded during reinstatement testing following bilateral intra-VTA administration of CRF (500 ng/side) in rats pretreated with intra-VTA injections of vehicle or 1 ng/side (A), 10 ng/side (B), or 20 ng/side (C) concentrations of the GABA_A receptor antagonist, bicuculline (BIC), and responding during the previous extinction (Ext) session. Intra-VTA CRF reinstated cocaine seeking regardless of whether rats were pretreated with vehicle or intra-VTA bicuculline (*P < 0.05 overall CRF reinstatement effect vs. Ext but no effect of BIC or CRF × BIC interaction).

3.5. Effects of intra-VTA 2-hydroxysaclofen injections on shock- and intra-VTA CRF-induced reinstatement

In contrast to bicuculline, bilateral injections of the GABA_B receptor antagonist, 2-hydroxysaclofen, into the VTA prevented reinstatement in response to either shock delivery or intra-VTA CRF. The effects of intra-VTA injections of the two 2-hydroxysaclofen concentrations tested (0.2 μg/side and 2 μg/side) on shock-induced cocaine seeking are shown in Fig. 5. Separate 2-way repeated measures (reinstatement × drug treatment) ANOVAs were conducted for each 2-hydroxysaclofen concentration. In both cases significant overall shock-induced reinstatement (0.2 μg/side: F_{1,4} = 153.84, P < 0.001, n = 5; 2 μg/side: F_{1,7} = 14.322, P < 0.01, n = 8) and significant interactions between 2-hydroxysaclofen and shock-induced reinstatement (0.2 μg/side: F_{1,4} = 91.274, P = 0.001, n = 5; 2 μg/side: F_{1,7} = 6.666, P < 0.05) were observed. Post-hoc testing showed that there was significant shock-induced reinstatement in rats pretreated with intra-VTA vehicle (P < 0.05) but not with either 2-hydroxysaclofen dose. Moreover, reinstatement following intra-VTA 2-hydroxysaclofen was significantly lower than following vehicle (0.2 μg/side, P < 0.05; 2 μg/side, P = 0.05).
Fig. 5. Effects of intra-VTA 2-hydroxysaclofen injections on shock-induced reinstatement. Data represent responding (lever presses/2-h session ± S.E.) recorded during reinstatement testing following electric footshock (0.5 mA, 0.5″ shocks delivered an average of every 40s over a 15-min period) in rats pretreated with intra-VTA injections of vehicle or 0.2 μg/side (A) or 2 μg/side (B) of the GABAB receptor antagonist, 2-hydroxysaclofen (2-HS) and responding during the previous extinction (Ext) session. Shock reinstated cocaine seeking following vehicle (0 μg/side) pretreatment (*P < 0.05 vs. Ext) but not following injections of 0.2 or 2 μg/side 2-hydroxysaclofen into the VTA. Moreover, lever pressing during the reinstatement session following shock delivery was significantly lower in rats that received intra-VTA injections of 0.2 or 2 μg/side 2-hydroxysaclofen relative to rats pretreated with vehicle (#P < 0.05 vs. 0 μg/side). By contrast, in rats with misplaced cannula that received 2-hydroxysaclofen injections into brain regions adjacent to the VTA, 2-hydroxysaclofen (2 μg/side) failed to affect shock-induced reinstatement of cocaine seeking (C).

To confirm anatomical localization of 2-hydroxysaclofen effects to the VTA, we also examined shock-reinstatement in a separate group of rats that received 2 μg/side 2-hydroxysaclofen injections via guide cannula implanted into regions adjacent to the VTA (n = 5; Fig. 5C). 2-hydroxysaclofen had no effect on shock-induced reinstatement in these rats. A 2-way ANOVA showed a significant overall reinstatement effect (F1,4 = 109.606, P < 0.001) but no effect of 2-hydroxysaclofen and no reinstatement × 2-hydroxysaclofen interaction.

The effects of intra-VTA injections of the two 2-hydroxysaclofen concentrations (0.2 μg/side and 2 μg/side) on cocaine seeking in response to intra-VTA CRF are shown in Fig. 6. As was the case with shock, significant overall intra-VTA CRF-induced reinstatement (500 ng/side: F1,4 = , P < 0.001, n = 5; 2 μg/side: F1,7 = , P < 0.01, n = 8) and significant interactions between 2-hydroxysaclofen and CRF-induced reinstatement (0.2 μg/side: F1,4 = P = 0.001, n = 5; 2 μg/side: F1,7 = , P < 0.05) were observed. Post-hoc testing showed that there was significant CRF-induced reinstatement in rats pretreated with intra-VTA vehicle (P < 0.05) but not but not with either 2-hydroxysaclofen dose. Additionally, reinstatement following intra-VTA
2-hydroxysaclofen was significantly lower than that observed following vehicle pretreatment (0.2 μg/side, P < 0.05; 2 μg/side, P = 0.05).

![Figure 6](image)

**Fig. 6.** Effects of intra-VTA 2-hydroxysaclofen injections on CRF-induced reinstatement of extinguished cocaine seeking. Data represent responding (lever presses/2-h session ± S.E.) following bilateral intra-VTA administration of CRF (500 ng/side) in rats pretreated with intra-VTA injections of vehicle or the 0.2 μg/side (A) or 2 μg/side (B) concentration of the GABA<sub>B</sub> receptor antagonist, 2-hydroxysaclofen (2-HS) and responding during the previous extinction (Ext) session. Intra-VTA CRF reinstated cocaine seeking following vehicle (0 μg/side) pretreatment (*P < 0.05 vs. Ext) but not following pretreatment with 0.2 or 2 μg/side 2-hydroxysaclofen. Moreover, lever pressing during the reinstatement session following CRF administration was significantly lower in rats pretreated with 0.2 or 2 μg/side 2-hydroxysaclofen relative to rats pretreated with vehicle (#P < 0.05 vs. 0 μg/side).

3.6. **Effects of intra-VTA bicuculline or 2-hydroxysaclofen injections on food-reinforced responding**

To determine if non-specific behavioral suppression contributed to effects on cocaine seeking, separate groups of rats were tested for effects of intra-VTA drug (10 or 20 ng/side bicuculline or 0.2 or 2 μg/side 2-hydroxysaclofen) or vehicle administration on lever-pressing reinforced by sucrose-sweetened food pellets during a 30-min session (Table 2; n = 4–6/group). Two-way testing (baseline vs. test session preceded by VTA injection; within subjects) × drug (drug vs. vehicle; between subjects) ANOVAs failed to show effects of injection of any of the drugs into the VTA on food-reinforced responding (no significant effects of testing or drug or testing × drug interactions were observed.

4. Discussion

Our results demonstrate that intra-VTA injections of the GABA_B receptor antagonist, 2-hydroxyasaclofen, prevent reinstatement in response to either footshock stress or intra-VTA delivery of the stressor-responsive neuropeptide, CRF. These effects were observed at 2-hydroxyasaclofen doses that did not alter lever pressing reinforced by sucrose-sweetened food pellets and did not affect cocaine seeking in the absence of stress or CRF. By contrast, intra-VTA injections of the GABA_A receptor antagonist, bicuculline across a range of doses, had no effects on shock- or CRF-induced reinstatement. Thus, the results suggest that 1) GABA release into the VTA and GABA_B receptor activation are necessary for stress-induced cocaine seeking and 2) in the VTA, GABA_B receptor activation is required for local CRF effects that underlie stress-induced cocaine seeking.

The ventral tegmental area (VTA) is a key site at which inputs from a number of stress-responsive brain regions converge to regulate motivated behavior and reward and promote relapse to drug use in addicts. Understanding the mechanisms in the VTA through which stressors trigger cocaine use should facilitate the development of new and more effective treatment strategies. We and others have previously reported that CRF actions in the VTA are required for stress-induced reinstatement following cocaine self-administration and that CRF delivery into the VTA is sufficient induce cocaine seeking (Wang et al., 2005, Wang et al., 2007, Blacktop et al., 2011 and Vranjkovic et al., 2014). These actions have been reported to involve both CRF-R1 (Blacktop et al., 2011 and Chen et al., 2014) and CRF-R2 (Wang...
et al., 2005 and Wang et al., 2007) receptors as well an interaction with the CRF binding protein (Wang et al., 2007). As is the case with many neuropeptides, the cellular effects of CRF in the VTA appear to involve a complex coordination of cellular function through a wide array of actions at presynaptic, postsynaptic and extrasynaptic sites.

Much of the research examining CRF actions in the VTA has focused on its enhancement of excitatory neurotransmission (Wise and Morales, 2010). CRF directly excites dopamine and non-dopamine neurons in the VTA (Korotkova et al., 2006 and Wanat et al., 2008) and indirectly facilitates excitatory synaptic transmission in the VTA through post-synaptic trafficking of NMDA and AMPA receptors (Ungless et al., 2003 and Hahn et al., 2009) and promotion of glutamate release (Wang et al., 2005 and Hahn et al., 2009). Stress-induced reinstatement following cocaine (Wang et al., 2005) or heroin SA (Wang et al., 2012) is associated with increased VTA glutamate levels, while intra-VTA delivery of kynurenic acid, an ionotropic glutamate receptor antagonist, prevents stress-induced reinstatement and corresponding increases in VTA dopamine levels (Wang et al., 2005 and Wang et al., 2012).

Less attention has been given to the role of VTA GABAergic neurotransmission in stress-induced drug seeking. Delivery of a combination of the GABA_A receptor agonist, muscimol, and the GABA_B receptor agonist, baclofen, into the VTA attenuates cocaine seeking in response to a number of stimuli, including a cocaine priming injection (McFarland and Kalivas, 2001), a cocaine-paired conditioned stimulus (Di Ciano and Everitt, 2004), and footshock stress (McFarland et al., 2004). However, while these studies implicate the VTA in cocaine seeking, they provide limited mechanistic information regarding the precise role of GABA as they do not differentiate between the contributions of GABA_A versus GABA_B receptors and since, in contrast to agonist-based approaches, they do not differentiate between GABAergic mechanisms that are active during stress and those that are not.

The actions of GABA in the VTA are complex. The VTA receives GABAergic inputs from a number of brain regions, including the nucleus accumbens (Yim and Mogenson, 1980 and Bocklisch et al., 2013), periaqueductal gray (Omelchenko and Sesack, 2010), bed...
nuclei of the stria terminalis (Kudo et al., 2012), lateral septum (Luo et al., 2011), laterodorsal tegmentum (Omelchenko and Sesack, 2005), ventral pallidum (Mahler et al., 2014), and rostromedial tegmental area (Jhou et al., 2009, Matsui and Williams, 2011 and Barrot et al., 2012). Moreover, VTA cell populations include GABAergic interneurons (Steffensen et al., 1998 and Cruz et al., 2004) and GABAergic projection neurons (Van Bockstaele and Pickel, 1995 and Carr and Sesack, 2000) that may provide collateral GABA mediated regulation within the region (Omelchenko and Sesack, 2009). Both GABA\textsubscript{A} and GABA\textsubscript{B} receptors are expressed on dopaminergic and non-dopaminergic cells in the VTA (Churchill et al., 1992, Wirtshafter and Sheppard, 2001, Okada et al., 2004 and Ciccarelli et al., 2012) where they can regulate excitability, signaling and neurotransmitter release (see Creed et al., 2014 for review).

Stress-induced cocaine seeking is associated with altered GABAergic synaptic transmission in the VTA (Graziane et al., 2013). However, the mechanism through which GABAergic signaling contributes to cocaine seeking and its relationship to CRF has not been previously reported. It has been suggested that CRF-releasing terminals in the VTA, at least those that innervate dopamine neurons, are predominantly glutamatergic, based on synaptic morphology (Tagliaferro and Morales, 2008). However, as is the case with most neuropeptides, regional diffusion of CRF to sites that regulate GABAergic transmission is likely. CRF has been reported to promote inhibitory transmission in a number of other brain regions including the central amygdala (Nie et al., 2004, Bajo et al., 2008 and Roberto et al., 2010), dorsal raphe nucleus (Waselus et al., 2005 and Kirby et al., 2008) and bed nucleus of the stria terminalis (Kash and Winder, 2006). In the VTA, CRF promotes GABA release via presynaptic receptor actions (Williams et al., 2014) as well as excitation of intrinsic GABA interneurons (Korotkova et al., 2006) and, through a postsynaptic CRFR1/GABA\textsubscript{B} receptor interaction, promotes GABA-induced GIRK-mediated inhibitory postsynaptic currents (Beckstead et al., 2009). Thus, the blockade of stress-induced cocaine seeking by 2-hydroxysalocafen could be attributable to 1) preventing the activation of GABA\textsubscript{B} receptors by GABA released in response to CRF and/or 2) disruption of a post-synaptic interactions between CRF and GABA\textsubscript{B} receptors.
The exact mechanism through which CRF interacts with GABA<sub>B</sub> receptors in the VTA to promote cocaine seeking is unclear but likely involves one of several possibilities. First, GABA<sub>B</sub> receptor activation could inhibit VTA GABAergic interneurons, thereby disinhibiting dopamine neurons that project to terminal field regions involved in stress-induced drug seeking such as the prelimbic cortex (Capriles et al., 2003 and McFarland et al., 2004) and nucleus accumbens (Shaham and Stewart, 1996 and Xi et al., 2004). It has been reported that, in contrast to VTA dopamine neurons, which are relatively insensitive to inhibition by the GABA<sub>B</sub> receptor agonist, baclofen, VTA GABA neurons are much more susceptible to baclofen inhibition (Bonci and Malenka, 1999 and Cruz et al., 2004; but see Margolis et al., 2012), due in part to increased coupling of GABA<sub>B</sub> receptors to GIRK channels (Cruz et al., 2004). In fact, long-term potentiation at inhibitory synapses between descending D1 receptor-expressing nucleus accumbens GABAergic medium spiny neurons and VTA GABAergic interneurons, and the resulting downstream disinhibition of VTA dopamine neurons, have been shown to contribute to cocaine-induced increases in dopamine neuronal excitability (Bocklisch et al., 2013), while GABA-mediated interneuron suppression and the resulting disinhibition of dopamine neurons have been proposed to underlie context-induced reinstatement of cocaine seeking (Luo et al., 2011). Thus, to the extent that CRF selectively regulates GABAergic synapses on local interneurons via GABA<sub>B</sub> receptors, CRF inhibition of local interneuron populations and disinhibition of dopaminergic neurons could account for its effects on cocaine seeking. While intriguing, this possibility is inconsistent with the finding that VTA GABA<sub>B</sub> receptor antagonism does not decrease but rather increases the nucleus accumbens dopamine response to stress (Doherty and Gratton, 2007) and tends to be inconsistent with our own finding that VTA GABA<sub>A</sub> receptor antagonism using bicuculline, which should reproduce any effects of 2-hydroxysaclofen-mediated inhibition of VTA GABAergic interneurons, does not reinstate cocaine seeking.

Alternatively, shock, via CRF, could promote GABA actions to decrease or alter the pattern of firing of VTA dopamine neurons, thereby promoting cocaine seeking. Indeed, Tan et al. (2012) have reported that footshock excites VTA GABA interneurons while also inhibiting of a large majority of dopamine neurons, consistent with reports that, while footshock activates a subpopulation of dopamine neurons.
neurons (Brischoux et al., 2009), most VTA neurons show a shock-induced reduction in firing (Ungless et al., 2004). These findings are paralleled by reports that aversive stimuli often produce time-locked decreases in nucleus accumbens dopamine release, as measured using voltammetry (Badrinarayan et al., 2012, Roitman et al., 2008 and Oleson et al., 2012). While the possibility that stressors can promote cocaine seeking via reductions in the activity of mesolimbic dopamine neurons is inconsistent with the assumption that stress-induced drug seeking is mediated by elevated dopamine in the nucleus accumbens (Shaham and Stewart, 1996 and Xi et al., 2004; but see McFarland et al., 2004), we have recently reported that an aversive stimulus (intra-oral quinine delivery) that reduces dopamine levels in nucleus accumbens shell can reinstate cocaine seeking following self-administration in rats (Twining et al., 2015). Moreover, both quinine-induced cocaine seeking and quinine-induced reductions in nucleus accumbens dopamine levels are dependent on VTA CRF receptor activation (Twining et al., 2015).

Another possibility is that the effects 2-hydroxysaclofen on cocaine seeking are attributable to antagonism of presynaptic GABA$_B$ receptors on the terminals of afferent projections into the VTA. It is well established that presynaptic GABA$_B$ receptors are important regulators of vesicular neurotransmitter release (see e.g., Takahashi et al., 1998, Sakaba and Neher, 2003 and Padgett and Slesinger, 2010) and, in the VTA, GABA$_B$ receptors have been reported to regulate both GABA (Chen et al., 2015) and glutamate (Padgett et al., 2012) release. Cocaine seeking and dopamine neurons in the VTA are negatively regulated by GABAergic efferents from several brain regions, including the ventral pallidum (Mahler et al., 2014) and the rostromedial tegmental area (Huff and LaLumiere, 2015). Thus, it is possible that GABA$_B$ antagonism disinhibits these afferents, thereby promoting GABA release and GABA$_A$ receptor-mediated inhibition of dopaminergic neurons and cocaine seeking. As would be the case with interneuron inhibition, our finding that intra-VTA bicuculline does not increase cocaine seeking would suggest that, to the extent that this mechanism applies, GABAergic inputs are not providing baseline tonic inhibition of dopamine neurons in the VTA.

Alternatively, CRF-induced GABA release may exert heterosynaptic effects via GABA$_B$ receptors to regulate glutamatergic
transmission (Manzoni and Williams, 1999). Riegel and colleagues (Williams et al., 2014) have reported that CRF, via CRF-R2 receptor-mediated effects on GABA release, can promote GABA$_B$ receptor activation on glutamatergic terminals, thereby attenuating glutamate release and offsetting CRF-R1 receptor mediated increases in excitatory regulation of VTA dopamine neurons. It has been hypothesized that, following cocaine self-administration, this CRF-R2 receptor-driven inhibitory effect of GABA on excitatory transmission diminishes, resulting in a shift from inhibitory to excitatory regulation of dopamine neurons by CRF. While this represents an interesting mechanism through which CRF can regulate VTA dopamine neurons, according to this model, CRF effects on glutamatergic transmission in the VTA are no longer GABA$_B$ receptor-dependent after cocaine self-administration. Moreover, it is not clear how GABA$_B$ receptor attenuation of excitatory neurotransmission would result in reinstatement. Notably, an important distinction between that study and ours is the use of yohimbine in combination with non-extinguished response-contingent cocaine-associated cues as reinstating stimuli which may involve unique neurocircuitry and/or activate VTA inputs in addition to those that are stimulated by stress alone. Nonetheless, this proposed mechanism does not seem to account for our current findings.

When considering the possible contribution of VTA GABA to cocaine seeking it is also important to recognize that the regulation of neuronal firing patterns in the VTA by GABA is complex and does not necessarily result exclusively in inhibition of efferent pathways. Transient GABA-mediated inhibition may coordinate or synchronize regional network activity and/or prime neurons for excitation and burst firing. Indeed, it has been reported that GABAergic transmission in the VTA is critical for nicotine-induced excitation of dopamine neurons and associated behavioral responses (Tolu et al., 2013).

Neither administration of bicuculline nor 2-hydroxysaclofen into the VTA alone was sufficient to induce cocaine seeking. Although reinstatement by intra-VTA bicuculline or 2-hydroxysaclofen has not, to our knowledge, been previously reported, these results were somewhat surprising to us, particularly in the case of bicuculline, which has been found to elevate nucleus accumbens dopamine levels (Ikemoto et al., 1997), increase locomotor activity (Grubb et al.,
2002 and Lavezzi et al., 2015), and produce conditioned place preference (Laviolette and van der Kooy, 2001) when injected into the VTA and has been reported to be self-administered directly into the VTA in mice (David et al., 1997). As elevated dopamine in the nucleus accumbens (Cornish and Kalivas, 2000) and intra-accumbens delivery of dopamine receptor agonists (Bachtell et al., 2005 and Schmidt et al., 2006) have been reported to be sufficient for reinstatement of cocaine seeking, we predicted that intra-VTA GABA receptor antagonism would induce cocaine seeking, especially considering that GABA receptor agonist injections into the VTA suppress dopamine release (Yoshida et al., 1994), drug self-administration (Xi and Stein, 1999, Brebner et al., 2000 and Backes and Hemby, 2008), and reinstatement (McFarland and Kalivas, 2001, Di Ciano and Everitt, 2004 and McFarland et al., 2004). When considering the failure of GABA antagonists to induced cocaine seeking, the complexity of GABAergic regulation of the VTA and the understanding that distinct mechanisms contribute to reinforcement/reward vs. motivation/seeking should be taken into account. While it is possible that the antagonist doses used were insufficient to effectively target GABA receptors, we consider this unlikely, as the same 2-hydroxysaclofen doses attenuated reinstatement and we were unable to test higher intra-VTA bicuculline doses due to the emergence of seizure activity, as has been previously described (Echo et al., 2002).

To confirm that any GABA receptor antagonist effects on reinstatement were not attributable to non-specific behavioral disruption, separate groups of rats were tested for effects of intra-VTA antagonist injections on food-reinforced lever pressing. Neither bicuculline nor 2-hydroxysaclofen altered food-reinforced responding, suggesting that motor impairment likely did not contribute to 2-hydroxysaclofen-induced reductions in shock- and CRF-induced reinstatement. Considering that optogenetic stimulation of VTA GABA neurons impairs natural reward consumption (van Zessen et al., 2012), it is somewhat surprising that effects on food-reinforced responding were not observed. However, consistent with our findings, others have reported that GABA_A and GABA_B receptor antagonism in the VTA has minimal effects on feeding behavior (Echo et al., 2002, Ackerman et al., 2003 and Miner et al., 2010). When interpreting these findings, it is important to note that the rates of responding during the food-reinforced sessions (approximately 30
responses/minute) were much higher than those during the reinstatement sessions. For this reason, less-pronounced disruption of motor performance that could have contributed to the observed effects on cocaine seeking or increases in responding attributable to enhancement of food reward may not have been detectable under these conditions.

5. Conclusion

To summarize, our results suggest that stress-induced reinstatement of extinguished cocaine seeking requires VTA GABA\textsubscript{B} receptor activation, likely via a CRF-regulated mechanism. While the precise process through which CRF interacts with GABA\textsubscript{B} receptors remains to be determined, these findings provide novel insight into mechanisms that contribute to stress-induced relapse and therefore may guide the development of new therapeutic approaches aimed at relapse prevention.
