Abstract
Maintaining the vitality of the dental pulp, the highly innervated and highly vascular, innermost layer of the tooth, is a critical goal of any dental procedure. Upon injury, targeting the pulp with specific therapies is challenging because it is encased in hard tissues. This project describes a method that can effectively deliver therapeutic agents to the pulp. This method relies on the use of nanoparticles that can be actively steered using magnetic forces to the pulp, traveling through naturally occurring channels in the dentin (the middle layer of the tooth). This method can reduce the inflammation of injured pulp and improve the penetration of dental adhesives into dentin. Such a delivery method would be less expensive, and both less painful and less traumatic than existing therapeutic options available for treatment of injured dental pulp. This technique would be simple and could be readily translated to clinical use.

Graphical Abstract
In this manuscript, technology to steer and deliver drug-laden nanoparticles to the tooth pulp is described. This technology exploits naturally occurring dentinal tubules that extend from the dentin to the pulp, and magnetic forces to actively steer iron nanoparticles deep into the tooth structure. This technology was tested on rat molar teeth and in freshly extracted human teeth and can be used to deliver drug-laden nanoparticles to the pulp, or to enhance the bond strength of commercially available resin adhesives to the tooth dentin.

Magnet, Nanoparticles, Drug delivery, Pulp, Composite

Dentinal tubules are microscopic channels that extend outwards, through dentin, from the dental pulp (soft, inner layer of the tooth) to the enamel border (hard, outer layer). In humans, these tubules are 0.3–2 μm in diameter and usually taper and may exhibit branching as they approach the pulp. Dentinal tubules are abundant in dentin (middle layer) and their density ranges from 10–30 tubules per 100 μm² of dentin.¹ Dentinal tubules serve as an important route for the delivery of nutrients to the dentin from the pulp and contain: dentinal fluids, un-mineralized collagen, processes of cells that deposit dentin (odontoblasts), sensory nerve terminals and immunoglobulins and complement proteins that assist with the defense against microorganisms.¹ Dentists recognized the importance of these tubules decades ago and it is through these dentinal tubules that micromechanical retention of esthetic composite resin restorations is achieved.¹, ² It is also through these tubules that the by-products of bacterial fermentation attack the highly innervated and highly vascular, innermost layer of the tooth, the tooth pulp, and consequently, cause pulpitis and consequently dental pain.³, ⁴ Maintaining pulp vitality is a goal of any procedure on the tooth and a healthy pulp is necessary for tooth nutrition, innervation, and immunocompetency.⁵ However, since the pulp is encased in hard tissues, targeting pulpal tissues with specific therapies is challenging. Systemic pharmacologic treatments are not effective because they do not effectively reach the pulp and topical drug delivery would be more concentrated, more beneficial and would have a more favorable side-effect profile.⁶ Dentists have tried, with mixed results, passive diffusion and iontophoresis to propel charged minerals and therapeutic agents including potassium, fluoride, and bisphosphonates to reduce tooth sensitivity and treat invasive idiopathic resorption of the tooth.⁷, ⁸, ⁹, ¹⁰, ¹¹ Here, we describe and test an active therapeutic agent delivery method to the dental pulp. We exploit dentinal tubules and use external magnetic forces to transport drug-eluting nanoparticles through the dentinal tubules to the pulp. Unlike diffusion, which is a passive process, magnetic forces can be arranged to act in one direction;
they can actively transport substantially more drug to a target than either diffusion or iontophoresis, and can be designed/constructed so as to release drugs over an extended period of time. This gentle, non-invasive and active delivery method may prove effective in introducing therapeutic agents into the pulp, along with other dental applications that involve dentinal tubules.

**Methods**

**Nanoparticles**

To deliver prednisolone to the pulp, commercially available chitosan-coated nanoparticles (300 nm, chemicell nano-screenMAG/G-Chitosan-Prednisolone, lot 1704/15, size 300 nm, 25 mg/ml) were used. These particles were applied to experimental cavities in rat mandibular molar teeth (1 μl per tooth).

To improve penetration of resin adhesive to the pulp, iron nanoparticles fabricated by reduction method were used. These particles were produced by reducing iron (II) in the aqueous solution of iron (II) chloride tetrahydrate by sodium borohydride with the addition of polyvinylpyrrolidone (PVP, Mw = 40,000) as stabilizing ligands in a flask. The iron nanoparticles were collected by placing a magnet beneath the flask and washed with water to remove PVP. The nanoparticles were then coated with silica via the hydrolysis of tetraethyl orthosilicate (TEOS) in ethanol. A solution of methacryloxypropyltrimethoxysilate (KH570) in ethanol was then added into the reaction to introduce acrylate functional groups onto silica-coated nanoparticles. A magnet was used to collect the acrylate-functionalized magnetic nanoparticles. These nanoparticles were dispersed into a commercially available adhesive resin (Scotch Bond MultiPurpose, 3M) with the aid of a mechanical mixer (DAC 150 Speed mixer, Flacktek, Landrum, SC, USA). The control adhesive did not include any nanoparticles. For the restoration, composite resin (TPH, Caulk/Dentsply, Milford, DE) was used. All procedures involving adhesive resin and composite resin were carried out under safe yellow light.

**Animal anesthesia and preparation**

All experiments involving animals were performed under a University of Maryland Baltimore approved IACUC protocol and in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki). Adult male and female Long Evans Rats (n = 81; Charles River Laboratories) were used. Animals were anesthetized using ketamine/xylazine (100/10 mg/kg, I.P.) or isoflurane (5% for induction and 1-3% for maintenance). Anesthetized animals were placed on a surgical table on a regulated heating blanket in the supine position. A small horizontal metal bar secured to the surgical table was placed on top of the mandibular incisors and used to stabilize the mandible. A stereotaxic incisor holder was attached to the maxillary incisors and used to open the mouth. A microscope was used to visualize the teeth during preparation. A high speed dental hand piece was used to prepare rat mandibular molars. Irrigation with cold, sterile isotonic saline was applied every 5 seconds during preparation to avoid excessive heat and suction was applied at the same time to prevent saline from penetrating the animal’s airway. A round carbide bur was used (0.4 mm in diameter). The cavity preparation extended 0.25 mm into dentin. The cavities were left exposed for two weeks before nanoparticle treatment.

**Nanoparticle application in rats**

Animals were anesthetized using ketamine/xylazine (100/10 mg/kg, I.P.) or isoflurane (5% for induction and 1-3% for maintenance). The teeth were washed and cleaned thoroughly from debris. A magnet (maximum internal field:1.4T, surface field: 0.54T; BX0X0X0-N52; K&J Magnetics, Inc.) was placed under the mandible and prednisolone-eluting nanoparticles (1 μL, >180 million particles) were applied to the cavity. After 30 minutes, the magnet was removed and the cavity was washed using isotonic saline and suction. The cavity was then etched using 37% phosphoric acid, and primer and bonding agent (Scotch Bond MultiPurpose, 3M) were applied
and light-cured. Composite resin was applied and light cured and the restoration was finished and polished to ensure that it conforms to the tooth contours and that it is not sharp or rough.

Extraction of specimens
For qRT-PCR, the animals were deeply anesthetized with Ketamine/Xylazine and sacrificed. The mandibular teeth were immediately extracted and flash frozen using liquid nitrogen. The teeth were stored in −80 °C freezer until time of use. For histology, the animals were euthanized with sodium pentobarbital (100 mg/kg). The rats were perfused transcardially with buffered saline followed by 4% buffered paraformaldehyde. The mandibular jaw, containing the teeth was removed, decalcified, embedded in paraffin and sectioned.

qRT-PCR analysis
Primers for all SYBR assays were designed using Primer 3 (see http://www.ncbi.nlm.nih.gov/tools/primer-blast/index.cgi). Melting curve analysis was performed to ensure single-product amplification for all primer pairs. TaqMan® assays were obtained from Applied Biosystems. RT-PCR was performed on the ABI 7900HT Fast Real Time PCR System (Applied Biosystems) using assays specific for each gene of interest. For SYBR assays, each reaction well contained 5mL of Power SYBR Green PCR Master Mix (Applied Biosystems, Cat#4367659), cDNA equivalent to 20ng of total RNA and 400nM each of forward and reverse amplification primers in a reaction volume of 10mL. For TaqMan® assays, each reaction well contained 5mL of Gene Expression Master Mix (Applied Biosystems, Cat#4370074), cDNA equivalent to 20ng of total RNA and 0.5mL of 20X concentrated TaqMan® assay in a reaction volume of 10mL. Cycling conditions were as follows: 95°C for 10 minutes for polymerase activation, followed by 40 cycles of 95°C for 15 seconds and 60°C for 1 minute. Data analysis was performed using Sequence Detection System software from Applied Biosystems, version 2.4. The experimental Ct (cycle threshold) was calibrated against the endogenous control product GAPDH. Samples were analyzed for relative gene expression by the ΔΔCt method. Two-way Analysis of Variance (ANOVA) followed by Dunnet’s multiple comparison test was used for statistical analysis. A P < 0.05 was considered significant.

Histological analysis
Mandibular jaws containing the teeth were decalcified, embedded in paraffin and sectioned sagittally (7 μm thick) for histological evaluation. The sections were mounted on slides, deparaffinized and cleared using xylene. Filtered 0.1 % hematoxylin was used to stain the sections for 10 minutes then rinsed in distilled water. The sections were then stained with eosin and dehydrated using alcohol. Mounting medium was then applied and the slides were coverslipped before examination under the microscope. A calibrated Oral & Maxillofacial Pathology investigator evaluated all the slides for the following criteria: Pulp inflammation (range of scores 0-3, lower number indicates less inflammation), pulp vascularity (scores: 0-9, lower score indicates normal vascularity), the width of periodontal ligament (0-3, lower score indicates normal ligament with no fibrosis), and the presence of periapical inflammation (0-7, lower score indicates a normal periapical area). Five sections from each animal were evaluated. The sum of scores was calculated for each animal, and then averaged across animals in each group. The average cumulative score was compared across the groups using the Kruskal-Wallis test, a P < 0.05 was considered significant.

Tooth bonding
Human teeth were mounted in a PVC plastic tube. The occlusal one-third of the tooth crown was removed to expose the mid-coronal dentin using a low speed saw (IsoMet Low Speed Saw, Buehler Ltd., Illinois, USA). The distance from the occlusal surface of the dentin, to the bottom of the PVC tube was 25 mm. The dentin surface was polished with 600-grit SiC paper. The teeth were etched with 37% phosphoric acid gel for 15 s, and rinsed with distilled water. The primer was applied (Adper Scotchbond Multi-Purpose Primer, 3M ESPE) and the solvent was removed with a stream of air for 5 s. The adhesive (Adper Scotchbond Multi-Purpose Adhesive, 3M ESPE)
was then applied and a magnet (Neodymium N52, described above) was placed immediately below the tooth for a period of 3 minutes before light-curing for 10 s (Optilux VCL 401, Demetron Kerr, Danbury, CT). Composite resin was applied and light-cured for 60 s. In control experiments, control adhesive was applied without nanoparticles or magnetic pull. One-way ANOVA followed by Dunnett’s multiple comparison test was used to compare between the groups. A \( P < 0.05 \) was considered significant.

Scanning electron microscopy

The resin bonded discs were polished to a high gloss with 600-grit emery paper and 0.05μm alumina under a stream of water. The sections were demineralized in hydrochloric acid (HCl) solution (6mol/L) for 10 s, and deproteinated in 1% sodium hypochlorite (NaOCl) solution for 10 min. The sections were sputter-coated with gold and examined in a Hitachi SEM model S-2500 using an accelerating voltage of 15.0 kV.

The micromorphology at the dentin-restoration interface was randomly visualized under SEM for each specimen. To quantify resin tag length, a blinded investigator measured the length of each resin tag from the edge of the hybrid layer to the tip of the resin tag. An average resin tag length was calculated for each specimen from three randomly acquired SEM images of the dentin/tooth interface. The overall average resin tag length was calculated for each group (\( n = 5 \) teeth/group). To quantify resin tag density, the number of resin tags present relative to the width of field of view was calculated and averaged for each specimen. The average density was then averaged for each group. A Student “t” test was used to compare between the groups. A \( P < 0.05 \) was considered significant.

Results

To experimentally inflame the pulp, we prepared moderate-size experimental cavities localized to the dentin of rat mandibular molars. The cavities were left untreated for 2 weeks before undergoing treatment using prednisolone-eluting magnetic nanoparticles that were actively guided to the tooth pulp using strong external magnetic forces (Figure 1, A). In control experiments, untreated (naïve) teeth and teeth treated with the same nanoparticles, without magnetic pull, were used. The teeth were harvested at 3 different survival periods (2 weeks, 4 weeks and 6 months) to assess changes in expression of 4 different cytokines in the dental pulp.

![Figure 1](image.png)

Figure 1. The effect of prednisolone eluting nanoparticles on the expression of inflammatory cytokines and growth factors in the rat tooth pulp. (A) Experimental design: Experimental cavities were prepared in rat mandibular molar teeth and
Cavities were left exposed for 2 weeks. After two weeks, the cavities on one side of the mandible were treated with prednisolone-eluting nanoparticles and a magnet was placed under the jaw for 30 minutes. On the other side, nanoparticles were placed in the cavity for 30 minutes, but without magnetic pull. The teeth were then cleaned and restored with composite resin. After a survival period of 2 weeks, 4 weeks and 6 months, qRT-PCR was performed to study changes in the levels of (B) IL1β, (C) PDGFα, (D) TGFβ and (E) TNFα. * denotes significant statistical difference. Error bars indicate standard deviations.

The expression levels of interleukin 1 beta (IL1β) was significantly different between the control and experimental groups (F = 13.83, P < 0.001, ANOVA, Figure 1, B). IL1β was significantly elevated following cavity preparation and nanoparticle treatment 2 and 4 weeks after treatment in the experimental group, before approaching baseline values at the 6-month time point. IL1β levels were significantly reduced when prednisolone-eluting nanoparticles were actively pulled to the pulp compared to controls (no magnetic pull) 2 weeks after treatment (Figure 1, B).

The expression levels of platelet-derived growth factor alpha (PDGFα) (Figure 1, C) and transforming growth factor beta (TGFβ) (Figure 1, D) were also significantly different between the groups (PDGFα: F = 7.48, P < 0.001, TGFβ: F = 11.52, P < 0.001, ANOVA). Both of these cytokines followed a similar pattern to that of IL1β, with both being significantly elevated compared to untreated teeth, and their expression being significantly less in treated teeth at 2 weeks, when magnetic pull was applied, compared to controls. The levels of tumor necrosis factor (TNFα) were not influenced by cavity preparation or nanoparticle application (F = 1.197, P = 0.31, ANOVA, Figure 1, E).

We further evaluated the anti-inflammatory effects of magnetic delivery of therapeutic nanoparticles using histological evaluation of teeth that were pre-prepared with experimental cavities as described above. Magnetic delivery of prednisolone-eluting nanoparticles was most effective in reducing cytokine levels 2 weeks after treatment, and therefore, we focused our histological analysis on that time point. We evaluated the tooth pulp for the presence of inflammation, and changes in vascularity. We also evaluated the periodontal ligament for signs of widening, and the periapical area for signs of inflammation. In Figure 2, representative examples of sagittal sections through molar teeth obtained from naive, experimental and control animals are shown. Tissues from animals in which prednisolone-eluting nanoparticles were actively steered to the pulp exhibited scores that were not significantly different from those of tissues from untreated animals (P = 0.004, Kruskal-Wallis test, Table 1). In control animals, when no magnetic pull was performed, pulp and periodontal tissues scored significantly higher for signs of inflammation and tissue damage when compared to tissues obtained from untreated animals (Table 1). Taken together, these findings indicate that active steering of drug-eluting nanoparticles is necessary for the anti-inflammatory effects observed, further suggesting that iron nanoparticles, guided through dentinal tubules using magnetic forces, can serve as an effective drug delivery system to the pulp.

Values modified with the same superscript letter are not significantly different.

In addition to serving as vessels to deliver nutrients to and from the pulp, dentinal tubules play a significant role in facilitating the retention of composite resin restorations (esthetic fillings) that are commonly used to restore dental cavities. Dentinal tubules allow for the formation of resin tags that assist in mechanically anchoring these restorations to dentin. Therefore, we tested if our delivery system can be used to actively steer resin adhesives into dentinal tubules, and if such active guidance enhances the initial shear bond strength of composite resin to dentin. We used freshly extracted human third molar teeth, and a commercially available adhesive resin (Adper Scotch Bond, Multi-Purpose Adhesive, 3M) dispersed with acrylate-functionalized magnetic iron nanoparticles of various sizes (100-1000 nm, 2% w:v). We used this nanoparticle-doped adhesive, in combination with brief (3 min) external magnetic force application, to bond composite resin to prepared teeth (Figure 3, A). We discovered that shear bond strength of composite resin to dentin is significantly increased when the diameter of nanoparticles used was ≥ 600 nm ($F = 11.399, P < 0.001$, Figure 3, B). These findings indicate that actively guiding nanoparticle-doped adhesive into dentin enhances the initial bond strength of composite resin restorations to dentin and suggests that this active delivery method increases the probability of resin tag formation, improving the penetration of resins into dentin.

![Figure 3. The effect of iron nanoparticles on the shear bond strength of composite resin to dentin.](image)

To determine if magnetic pull does in fact improve the penetration of resin into dentin, we obtained scanning electron microscopy (SEM) images from cross sections of (1) teeth restored with the nanoparticle-doped adhesive and magnetic pull (900 nm, 2%, $n = 5$ teeth, 3 images/tooth), and (2) teeth restored with control adhesive (no nanoparticles, $n = 5$ teeth). Representative images are shown in Figure 4, A-B. Teeth restored using the nanoparticle-doped adhesive and magnetic pull displayed an extensive network of resin tags penetrating dentin, both vertically and horizontally, compared to control (Figure 4, A-B). The average length of resin tag and the number of resin tags per field of view were also significantly greater in teeth restored with the nanoparticle-doped adhesive compared to controls (Figure 4, C-D). These findings further emphasize the utility of iron nanoparticles and magnetic forces as a delivery system in dental applications.
Discussion

This project describes a non-invasive delivery method that exploits naturally occurring dentinal tubules, and uses magnetic forces, to actively steer therapeutic agents to the dental pulp. We demonstrate that such methods can reduce the expression of inflammatory cytokines and reduce the inflammation of injured pulp. The results also indicate that this delivery method can be used to improve the penetration of dental adhesives into dentin, which enhances the shear bond strength of composites to dentin.

Nanoparticles are used routinely in dentistry. They are an integral component of esthetic fillings, porcelains, cements, and mineralized bone scaffolds. To target pulpal tissues, we used nanoparticles that are commercially available Chemicell (Berlin, Germany). These particles consist of an iron oxide core coated with polysaccharides (starch or chitosan) to confer biocompatibility. Chitosan-coated nanoparticles were used in this project because chitosan-coated nanoparticles may be more beneficial than starch-coated nanoparticles. Particles coated with chitosan can ionically bind greater drug loads due to their high zeta potential (+23 mV). These particles can, in turn, be loaded with drugs such as steroids (e.g.: prednisolone). These particles have been tested and determined to be biocompatible and non-toxic in both preclinical models and in human clinical trials where they were shown to be biocompatible in quantities much greater than the amounts used in this project, as such, the particles themselves are likely to have minimal effect on pulpal biology. These particles have also been used with great success to treat inner and middle ear diseases and this delivery method may be instrumental in treating pulpal conditions that are refractory to current treatments, such as invasive cervical resorption of the dental pulp.

Properties that regulate the penetration of materials across dentinal tubules have been subjected to considerable study. Thus, particle size will significantly influence the amount of drugs that can be delivered to the pulp. The most effective particle size will depend on both the applied magnetic forces and the resistance to motion within the tubules, including resistance due to pulpal pressure. For a single particle, the magnetic force varies with particle volume (with the cube of particle diameter). If the particles are too small, they may not experience sufficient magnetic force; if they are too large, they may aggregate rendering them difficult to move through the narrow tubules. Only one size of nanoparticles (300 nm) was used to deliver nanoparticles to the pulp, and the force was applied for a period of 30 minutes. However, additional experiments are needed to assess the effect of particle size, and delivery time, on the efficiency of drug delivery to the pulp.
It is important to note that rat molar teeth are anatomically and developmentally similar to human teeth, albeit smaller in size \(^{27}\); and moreover, rat molar teeth exhibit dentinal tubules that are within the range of diameters reported for human dentinal tubules \(^{28}\); and the histologically observed healing of dental pulp tissue after injury in rats is comparable with the healing process described in humans and other mammals. \(^{29}\) Nonetheless, the results of this study are the first step in exploring the benefits of delivery of therapeautic agents locally to the dental pulp. The results generated from this study will be used to design future preclinical and clinical trials and test the utility of drug-laden nanoparticles for the treatment of dental disease.

This technology can also be used to improve bond strength of composite resins to dentin. A major concern with contemporary adhesive resins is their limited ability to infiltrate and penetrate demineralized dentinal collagen fibrils exposed by acid-etching or self-etch adhesives. This is due to inability of the adhesive to replace and remove loosely bound water around collagen fibrils \(^{30}\); and due to the presence of highly hydrated negatively charged proteoglycans in the interfibrillar spaces preventing the adhesive from penetrating deep into the dentin hybrid layer resulting in a weaker adhesive/dentin interface. \(^{31}\) This incomplete infiltration renders exposed collagen fibrils susceptible to enzymatic attack by metalloproteinases, which will degrade the composite bond to dentin and reduce its durability. \(^{32, 33, 34, 35}\) Therefore, an adhesive resin which improved penetration, as demonstrated in this study, could be used to provide for a successful, durable restoration. \(^{33, 36}\)

Incorporation of fillers into resin materials can produce adhesives with better mechanical properties, generating a stronger hybrid layer that is more resistant to degradation and water sorption, as shown in several studies. \(^{37, 38}\) Niobium pentoxide, colloidal silica, hydroxyapatite, ytterbium trifluoride, tantalum oxide, glass and zirconia are among the filler particles that have been tested. \(^{39, 40, 41, 42, 43, 44, 45}\) However, these studies yielded mixed results. Some studies reported improved mechanical properties and bond strength when filled adhesives were used, \(^{40, 41, 43, 46}\) while other studies showed no change, or deterioration in mechanical properties or bond strength. \(^{47, 48, 49}\) However, none of these studies actively pulled the fillers to penetrate dentin.

Furthermore, previous studies of nanofilled adhesives show that nanoparticles were mostly unable to penetrate the interfibrillar spaces due primarily to a difference in diffusion rate between monomers and particles. \(^{37}\) The reasoning for this possibly includes the presence of non-collagenous proteins and proteoglycans in the interfibrillar spaces which may exert steric hindrance for nanoparticle infiltration. \(^{44}\) The use of active force to steer the nanoparticles may assist in overcoming these limitations, however, future studies are needed to determine the ability of this method to penetrate interfibrillar spaces within dentin.

In our in vitro experiments, we are applied a single magnet under the teeth to align the magnetic force with dentinal tubule direction. In clinical situations, this is possible for mandibular teeth where the magnet can be placed under the chin. Such an approach may be challenging for maxillary teeth. However, an array of extraoral magnets can be designed (e.g. Figure 5) to deliver strong perpendicular forces to the teeth, regardless of their position in the arch.
Figure 5. Custom made array made of 4 Neodymium N52 magnets (N = north pole of the magnet, S = south) for application of nanoparticles to maxillary teeth. To design this array, “Finite Element Method Magnetics” was used to compute the magnetic field and Matlab was used for optimization. Optimization was performed along a line 1.5 cm away from the face of the array. This configuration allows the pulling of nanoparticles apically in maxillary teeth, and mandibular teeth if necessary. Black lines represent magnetic fields.

The active delivery method we describe relies on iron nanoparticles and magnetic forces. This method exploits naturally occurring dentinal tubules, and can be used to deliver medications to reduce pulpal inflammation, and to enhance bond strength of composite resin to dentin. Such a delivery method is economical, less invasive and pain-free. It can allow for intervention at an earlier stage of the disease, i.e., before the pulp dies. The technique would be simple and could be readily translated to clinical use.
