Abstract: The analytical calculation of the bit error rate (BER) of digital optical receivers that employ avalanche photodiodes (APDs) is challenging due to 1) the stochastic nature of the avalanche photodiode’s impulse-response function and 2) the presence of intersymbol interference (ISI). At ultrafast transmission rates, ISI becomes a dominant component of the BER, and its effect on the BER should be carefully addressed. One solution to this problem, termed the bit-pattern-dependent (PD) approach, is to first calculate the conditional BER given a specific bit pattern and then average over all possible bit patterns. Alternatively, a simplifying method, termed the bit-pattern-independent (PI) approach, has been commonly used whereby the average bit stream is used to calculate the distribution of the receiver output, which, in turn, is used to calculate the BER. However, when ISI is dominant, the PI approximation is inaccurate. Here, the two approaches are analytically compared by analyzing their asymptotic behavior and their bounds. Conditions are found to determine when the PI method overestimates the BER. The BER found using the PD method exponentially decays with the received optical power, whereas for the PI approach, the BER converges to a constant, which is unrealistic. For an InP-based APD receiver with a 100-nm multiplication layer, the PI method is found to be inaccurate for transmission rates beyond 20 Gb/s.

Index Terms: Bit error rate (BER), optical receivers, Gaussian distribution, photodetectors, intersymbol interference (ISI), analytical models, approximation error.

1. Introduction

Avalanche photodiodes (APDs) are commonly used photodetectors in many high-speed optical receivers due to their internal optoelectronic gain, which allows the photogenerated current to dominate the thermal noise without the need for optical pre-amplification of the received optical signal. The physical phenomenon behind the internal current gain is the electron-hole impact ionization process,
which takes place in the high-field (intrinsic) multiplication layer of the APD [1]. However, the enhancement from the gain is accompanied by excess in the shot noise by a factor known as the excess noise factor, which is a measure of uncertainty associated with the stochastic nature of the APD’s gain. Moreover, the APD’s buildup time, which is the stochastic time required for the cascade of impact ionizations to complete per incident photon, further limits the receiver performance by causing intersymbol interference (ISI). While separate absorption and multiplication InP APDs have been successfully deployed in 10 Gb/s lightwave systems, they cannot sustain higher bit rates due to their long avalanche buildup time. Much of the recent work on APDs has focused on developing new structures and incorporating alternative materials that will yield lower noise and higher speed. For example, in 2009, a Ge/Si APD was demonstrated to have a gain-bandwidth product of 340 GHz and a sensitivity of −28 dBm [2] at 10 Gb/s. Moving toward higher transmission speed, a new approach has been proposed in [3], [4] that employs periodic bit-synchronized dynamic biasing of the APD to reduce ISI by quenching the avalanche buildup time near the end of each optical pulse. The analytical calculation of the bit-error rate (BER) of digital optical receivers that employ APDs is especially challenging due to the presence of ISI and the stochastic nature of avalanche gain and its correlation with the stochastic avalanche buildup time.

Numerous methods have been developed to approximate the BER. In [5], a procedure was given to numerically compute system performance, which uses the nearly exact Webb’s approximation of the true Conradi distribution for the APD output. The measured performance of the system was found to be in excellent agreement with the performance predicted. In their model, the ISI was not addressed due to the low transmission speed. However, as it is the case in modern lightwave systems, the transmission rates are large (upwards of 10 Gb/s) and the ISI cannot be neglected. Sun et al. [6] developed a method to compute the exact BER based on the moment-generating function (MGF). The effects of ISI as well as the APD’s dead space are both included in the analysis. The exact BER was computed by adding the contribution of every photon absorbed by the APD during every bit interval to the receiver output. However, this exact method is computationally expensive and provides no closed-form expression for the BER.

In many cases, a closed-form expression for the BER is required to understand, predict and provide analytical insight for the receiver performance. A closed-form expression for the BER can be found by first conditioning on the past bit pattern; then the BER is calculated by averaging the conditional BER over all possible past bit patterns. This approach, denoted here by the bit-pattern–dependent (PD) approach, was adopted by Ong et al. [7], [8] in which the receiver output, conditional on the present and all the past bits, is approximated by a Gaussian random variable. The validity of this approximation has been verified for large number of incident photons [9]. The Gaussian approximation has been shown to be quite accurate in estimating the bit error probabilities [10]. On the other hand, to simplify the analysis, another method has been commonly used by conditioning on the current bit while considering the average of all possible bit patterns (in place of the individual realizations of bit patterns) to generate the Gaussian distribution of the output [11]–[13]. Hence, the receiver output in this approach is bit-pattern–independent (PI), as it depends only on the average past bit pattern. However, the benefit from the simplification comes at the expense of inaccuracy in the BER when ISI is dominant, i.e., when transmission speed is very high as in the OC-192 standard.

This paper analyzes the closed-form expressions of the BER found using the PI and PD methods and studies their accuracy. To do so, the asymptotic behavior and the analytical bounds of each method are derived. By comparing the results to the numerical computed BER [6], it is found that at high transmission speeds, the PD method can give a much more accurate approximation of the BER than that offered by the PI method. This inaccuracy is negligible for low-speed applications (e.g., at 10 Gb/s) in which the ISI does not have a significant impact on the current bit. It is important to realize that even at such relatively low speed, the ISI still exists and by completely neglecting it, the BER will be underestimated. Therefore, from the asymptotic behavior, we find a photocount threshold that can be used as a decision rule to determine which approach should be used. When the photocount is below the threshold, the PI method can be adopted as a simplified approach. However, after
exceeding the photocount threshold, ISI should be properly addressed by conditioning on the entire bit pattern stream as done by the PD approach.

2. Review of Relevant BER Models
Consider a typical non-return-to-zero, on-off keying optical communication system incorporating an APD-based integrate-and-dump receiver. When an information bit 1 is transmitted, an optical pulse is transmitted in a time interval of duration $T_b$; otherwise, no pulse is transmitted. Let $B_n$ denote the input binary sequence representing the binary information in the $n$th bit ($n = 0$ represents current bit). Let $\Gamma$ denote the raw output resulting from the integrate-and-dump receiver (i.e., prior to any decision). The information (0 or 1) can be detected by comparing $\Gamma$ to a threshold, $\theta$. Each information bit $B_n$ contributes a term $R_n B_n$ to the receiver output, where $R_n$ is the random variable representing the stochastic receiver output when the $n$th past bit is a 1 and all other past bits are 0. Thus, the receiver outputs conditioned on the current bit ($B_0 = 0$ or 1), denoted by $\Gamma_0$ and $\Gamma_1$, respectively, can be expressed as

$$\Gamma_0 = \sum_{n=1}^{\infty} R_n B_n + N$$
$$\Gamma_1 = \sum_{n=1}^{\infty} R_n B_n + R_0 + N$$

where $N$ is the receiver Johnson noise. Note that only the term $R_0$ conveys information from the current bit. The components $R_n$, $n \geq 1$, represent the ISI contributions in the receiver output from the earlier bits. Due to the analytical complexity of the exact statistics of $R_n$, it is customary to model $R_n$ as a Gaussian random variable.

For its relevance to the present paper, we begin by briefly reviewing the probabilistic model for the conditional receiver outputs, $\Gamma_0$ and $\Gamma_1$, developed using the PI and PD methods to determine their BERs; these BERs are termed BER$_I$ and BER$_D$. Both the mean and variance of $R_n$, denoted by $\mu_n$ and $\sigma_n^2$, respectively, are shown in [7] to be proportional to the average number of photons per bit, $n_0$. Additionally, they are both exponentially decreasing with the bit order $n$. More precisely [7],

$$\mu_0 = n_0 \beta_0$$
$$\mu_n = n_0 e^{-\kappa \lambda} \alpha_n \quad (n = 1, 2, \ldots)$$
$$\sigma_0^2 = n_0 \beta_\sigma$$
$$\sigma_n^2 = n_0 e^{-\kappa \lambda} \alpha_n \quad (n = 1, 2, \ldots).$$

The coefficients $\alpha_\mu$, $\alpha_\sigma$, $\beta_\mu$, and $\beta_\sigma$ are APD-specific system parameters derived in [7] as

$$\beta_\mu = \frac{\langle G \rangle}{\kappa \lambda} (\kappa \lambda - 1 + e^{-\kappa \lambda})$$
$$\beta_\sigma = \frac{\langle G \rangle^2 F}{\kappa \lambda} (\kappa \lambda - 2 + 2e^{-\kappa \lambda} + \kappa \lambda e^{-\kappa \lambda})$$
$$\alpha_\mu = \frac{2\langle G \rangle}{\kappa \lambda} (\cosh(\kappa \lambda) - 1)$$
$$\alpha_\sigma = \frac{\langle G \rangle^2 F}{\kappa \lambda} (e^{-\kappa \lambda} - 1)(1 - \kappa \lambda e^{-\kappa \lambda} - e^{-\kappa \lambda})$$

where brackets represent ensemble average and $F$ is the APD’s excess noise factor, defined as $F = \langle G^2 \rangle / \langle G \rangle^2$. Sun et al. [11] defined the so-called shot-noise-equivalent-bandwidth as $B_{\text{sneq}} = \langle G^2 / T \rangle 2 \langle G \rangle^2 F$, the bandwidth correlation factor as $\kappa = 4B_{\text{sneq}} / 2\pi B_{\text{3dB}}$, and the detector’s relative speed as $\lambda = 2\pi B_{\text{3dB}} T_b$. The ensemble average quantities can be computed using the joint probability
density function (PDF) associated with the random variables comprising the APD’s stochastic gain, $G$, and its stochastic avalanche duration time, $T$, developed in [11].

The PI method used in [11] approximates the conditional receiver outputs, $\Gamma_0$ and $\Gamma_1$, by Gaussian random variables. In particular, BER$_i$ is computed as [11]

$$\text{BER}_i = \frac{1}{2} \text{erfc} \left( \frac{\mu_{i1} - \mu_{i0}}{\sqrt{2}(\sigma_{i0}^2 + \sigma_{i1}^2)} \right)$$

(10)

where $\mu_{i0}$ and $\sigma_{i0}^2$ denote the mean and variance of the receiver output conditional on the present bit being 0 while assuming the average of all possible patterns, i.e., $B_n = 1/2$ for $n \geq 1$. Moreover, $\mu_{i1}$ and $\sigma_{i1}^2$ are similar quantities conditional on the present bit being 1. The expressions for the parameters $\mu_{i0}$, $\sigma_{i0}^2$, $\mu_{i1}$, and $\sigma_{i1}^2$ are [11]

$$\mu_{i0} = \frac{1}{2} e^{-\kappa \lambda} \frac{n_0 \alpha_d}{1 - e^{-\kappa \lambda}}$$

(11)

$$\mu_{i1} = \mu_{i0} + \beta \mu n_0$$

(12)

$$\sigma_{i0}^2 = \frac{1}{4} \sum_{n=1}^{\infty} (2\sigma_n^2 + \mu_n^2) + \sigma_N^2$$

(13)

$$\sigma_{i1}^2 = \sigma_{i0}^2 + n_0 \beta_s.$$  

(14)

The optimal decision threshold, $\theta$ that minimizes BER$_i$ is [1]

$$\theta = \frac{\mu_{i1} \sigma_{i0} + \mu_{i0} \sigma_{i1}}{\sigma_{i1} + \sigma_{i0}}.$$  

(15)

Note that in the PI method, the distribution of the conditional receiver output has a unimodal distribution.

We next describe the PD method. Instead of assuming a Gaussian PDF for the receiver output conditional on the present bit, Ong et al. [7] assume a Gaussian PDF for the receiver output conditional on the present and the entire past bit stream. This will lead to a multimodal distribution for the conditional receiver output.

More precisely, for an arbitrary past bit pattern, $l_j \in \{0, 1\}^\infty$, the pattern-dependent means and variances of $\Gamma_0$ and $\Gamma_1$ are given by [7]

$$\mu_{D0}(l_j) = \sum_{k=1}^{\infty} a_k(l_j) \mu_k$$

(16)

$$\mu_{D1}(l_j) = \mu_{D0}(l_j) + \mu_0$$

(17)

$$\sigma_{D0}^2(l_j) = \sum_{k=1}^{\infty} a_k(l_j) \sigma_k^2 + \sigma_N^2$$

(18)

$$\sigma_{D1}^2(l_j) = \sigma_{D0}^2(l_j) + \sigma_0^2$$

(19)

where $a_k(l_j) = 0$ unless the $k$th bit in the pattern $l_j$ is a 1 bit, in which case $a_k(l_j)$ assumes the value 1. To calculate BER$_D$, Ong et al. compute the ensemble average of the pattern-specific BER over all possible past bit patterns: [7]

$$\text{BER}_D = \lim_{L \to \infty} \frac{1}{2^L} \sum_{j=1}^{2^L} \frac{1}{4} \left[ \text{erfc} \left( \frac{\theta - \mu_{D0}(l_j)}{\sqrt{2} \sigma_{D0}(l_j)} \right) + \text{erfc} \left( \frac{\mu_{D1}(l_j) - \theta}{\sqrt{2} \sigma_{D1}(l_j)} \right) \right]$$

(20)

where $\theta$ is calculated for convenience from (15). Note that the optimal threshold, denoted by $\theta_o$, does not have a simple analytical expression in this case because the PDF of the receiver output is a multimodal distribution. However, one can calculate $\theta_o$ numerically by finding the intersection point of the conditional PDFs of the receiver output. In the calculations considered in Section 4, we evaluate
BER\textsubscript{D,opt} using the optimal threshold, \(\theta_0\), and compare it to BER\textsubscript{D}, which uses the threshold \(\theta\). Note that we have implicitly neglected the additional current generated from the background light and tunneling. Nonetheless, the above models can be easily generalized to accommodate the dark current and the background light rates. These effects will only shift the means and increase the variances of the receiver output by adding additional interference and noise. Therefore, ignoring these effects will not influence the conclusions of this paper.

Fig. 1 shows an example of the conditional PDFs calculated for an InP-based APD with 100-nm multiplication layer. An electric field of 10.5 kV/cm was assumed in the multiplication layer, corresponding to an average gain of 10.3 and a buildup-time–limited 3-dB bandwidth of 29 GHz. The bit transmission rate is set to 60 Gb/s. The PDFs of \(\Gamma_0\) and \(\Gamma_1\) for the PI and PD approaches are compared to the exact PDFs found in [6]. For a linear-mode operation of the APD, the avalanche buildup time terminates at some finite random time almost surely. Therefore, in the PD approach, we can justify setting an adequate value for \(L\) to be sufficiently large to capture all the ISI terms. In our calculation, we found \(L = 5\) as an appropriate value beyond which no significant change in the BER was observed. Fig. 1 foretells that the PD method yields a better approximation of the exact PDF compared to the PI approach. Also, it is clear from the figure that BER\textsubscript{D} (as well as the exact BER) outperforms BER\textsubscript{I} since the PDFs of the PI method are larger than that for the PD (and the exact) method in the vicinity of the decision threshold, \(\theta\).

3. Asymptotic Analysis of the BER

We now compare BER\textsubscript{I} and BER\textsubscript{D} for large \(n_0\) and for various transmission rates, \(1/T_b\).

3.1.1. Theorem 1

\[ \lim_{n_0 \to \infty} \text{BER}_I = \text{constant whereas BER}_D \text{ decays exponentially in } n_0. \]

Moreover, when \(n_0\) exceeds the threshold

\[ n_{th} = -\frac{1}{c_2^2} \ln \left[ \sqrt{\pi} \text{erfc} \left( \frac{\beta \sqrt{1 - e^{-2\gamma_0 \lambda}}}{\sqrt{2e^{-\gamma_0 \lambda} c_2}} \right) \right] \]  \hspace{1cm} (21)

where \(c_2\) is defined in (26), then \(\text{BER}_I - \text{BER}_D > r(n_0)\), where \(r(n_0)\) is a monotonically increasing positive function converging to \(\lim_{n_0 \to \infty} \text{BER}_I\).
Before proving this theorem, it is worthwhile to mention that the photon count threshold, \( n_0 \), is a function of the bit transmission speed, \( 1/T_b \), reflected in the detector’s relative speed factor, \( \lambda = 2\pi B_{3db} T_b \).

### 3.1.1.1. Proof

Consider the case for which the current bit is 0; in this case and for large \( n_0 \),

\[
\sigma_{n0}^2 \sim \frac{1}{4} \frac{e^{-2\lambda}}{1 - e^{-2\lambda}} \alpha_\mu^2 n_0^2.
\]  

(22)

Similarly, for the case when the current bit is 1, it can be shown that \( \sigma_{n1}^2 \sim \sigma_{n0}^2 \) when \( n_0 \) is large. Substituting these results in the error probability found in (10), we obtain

\[
\lim_{n_0 \to \infty} \text{BER}_I = \frac{1}{2} \text{erfc} \left( \frac{\sqrt{\frac{1}{2}} e^{-\lambda} \alpha_\mu}{\sqrt{2e^{-\lambda} \alpha_\mu}} \right).
\]  

(23)

Thus, \( \text{BER}_I \) is asymptotically independent of \( n_0 \) and it saturates to a predetermined constant.

Next, we find the upper bound, \( U(n_0) \), for \( \text{BER}_D \) and describe its asymptotic behavior. This is done by considering the worst (maximum error) bit-pattern scenario. Consider the first term in (20), which represents the probability of falsely announcing 1 when the current bit is 0. This term is maximized when all the past bits are 1. Similarly, the second term in (20), which represents the probability of falsely announcing 0 when the current bit is 1, is maximized when all the past bits are 0. By replacing these worst-case scenarios in (20), we obtain the following upper bound for \( \text{BER}_D \):

\[
\text{BER}_D < \frac{1}{4} \left[ \text{erfc} \left( \frac{\theta - \sum_{n=1}^{\infty} \frac{\alpha_n}{\sqrt{2}} \sigma_n}{\sqrt{\sum_{n=1}^{\infty} \sigma_n^2}} \right) + \text{erfc} \left( \frac{\mu_0 - \theta}{\sqrt{2\sum_{n=0}^{\infty} \sigma_n^2}} \right) \right].
\]  

(24)

Using the upper bound \( \text{erfc}(x) < \left( \frac{2}{\sqrt{\pi}} \right) \left( e^{-x^2} / x + \sqrt{x^2 + (4/\pi)} \right) \) \[14\], we further obtain

\[
\text{BER}_D < \frac{1}{4\sqrt{\pi}} \left( \frac{e^{-c_1^2 n_0}}{c_1 \sqrt{n_0}} + \frac{e^{-c_2^2 n_0}}{c_2 \sqrt{n_0}} \right) \equiv U(n_0)
\]  

(25)

where \( c_1 \) and \( c_2 \) are defined as

\[
c_1 = \frac{1}{2} \beta_\mu - \frac{e^{-\lambda} \alpha_\mu}{2(1 - e^{-\lambda}) \alpha_\mu} \quad \text{and} \quad c_2 = \frac{1}{2} \beta_\mu - \frac{e^{-\lambda} \alpha_\mu}{2(1 - e^{-\lambda}) \alpha_\mu}.
\]  

(26)

Similarly, to find a lower bound for \( \text{BER}_D \), we consider the best (minimum error) past-bit scenarios (a past-bit stream of all 0s when considering the probability of falsely announcing 1 and a past-bit stream of all 1s when considering the probability of falsely announcing 0). By using these best-case scenarios in conjunction with the lower bound \( \text{erfc}(x) > \left( \frac{2}{\sqrt{\pi}} \right) \left( e^{-x^2} / (x + \sqrt{x^2 + 2}) \right) \) \[4\], it can be shown that

\[
\text{BER}_D > \frac{1}{4\sqrt{\pi}} \frac{e^{-c_0^2 n_0}}{c_0 \sqrt{n_0}}
\]  

(27)

where \( c_0 = \beta_\mu / 2\sqrt{2\beta_\sigma} \). Therefore, unlike \( \text{BER}_I \), \( \text{BER}_D \) decays exponentially with respect to the average photon count \( n_0 \) since its upper and lower bounds decay exponentially in \( n_0 \).

Next, consider the intersection point between \( \lim_{n_0 \to \infty} \text{BER}_I \) and \( U(n_0) \), which can be approximated for large \( n_0 \) by \( n_m \) defined in (21). Note that when \( n_0 > n_m \), \( \text{BER}_I > \text{BER}_D \); furthermore, \( \text{BER}_I - \text{BER}_D > r(n_0) \) where \( r(n_0) = \lim_{n_0 \to \infty} \text{BER}_I - U(n_0) \). Clearly, \( r(n_0) \) is a monotonically increasing function in \( n_0 \) with \( \lim_{n_0 \to \infty} r(n_0) = \lim_{n_0 \to \infty} \text{BER}_I \).
4. Numerical Results

In our calculations, we selected an InP-based APD receiver with a 100-nm multiplication layer and an electric field of 10.5 kV/cm. The system parameters, calculated numerically using the renewal theory approach [11], are $\alpha_0 = 97.49$, $\alpha_1 = 5.5 \times 10^3$, $\beta_0 = 7.76$, and $\beta_1 = 325.4$. The bit-length parameter is set to $L = 5$, which is large enough to capture all significant ISI terms for this example. The behavior of $\text{BER}_I$, $\text{BER}_D$, and $\text{BER}_D^{\text{opt}}$, are shown in Fig. 2 for two transmission rates, 10 GHz and 30 GHz. We compare the results to the exact BER calculated using the MGF approach [6]. The numerical results suggest that at low transmission rate (10 Gb/s), the PI method gives a good estimate of the BER and it can be used instead of the PD method to reduce the computational complexity. However, at 30 Gb/s, ISI becomes crucial to the BER and the PI method deviates from the exact BER and saturates at high optical powers as the asymptotic analysis predicted. On the
other hand, for the PD method, both BER\subscript{D} and BER\subscript{D,opt} decay exponentially and follow the exact BER with a small difference. This difference is due to the Gaussian approximation of the actual PDFs, which are, unlike the normal distribution, asymmetric about the mean value. Therefore, we conclude that the PD method offers a better approximation to the exact BER than the PI method at high transmission rates.

The asymptotic analysis found in Section III is included in Fig. 2(b). At 10 Gb/s the photon count threshold was found from (21) to be large enough \(n_{th} \approx 10^4\) that the advantage of the PD method over the PI method is not realizable for any reasonable value of \(n_0\). However, by increasing the transmission speed to 30 Gbps, \(n_{th}\) drops dramatically to 1500 photons per bit, as shown in Fig. 2(b). Clearly at such speed the PI method is invalid and the PD method must be used. Fig. 3 illustrates BER\subscript{i} – BER\subscript{D} at different transmission speeds. It is observed that the discrepancy between BER\subscript{i} and BER\subscript{D} widens with the transmission rate. At lower transmission rates such as 10 Gb/s, where ISI is not severe, the PI and PD methods are almost equivalent. However, at higher transmission rates, e.g., \(R = 30\) Gb/s, BER\subscript{i} – BER\subscript{D} = 2.9 \times 10^{-7} when \(n_0 = 1000\), and BER\subscript{i} – BER\subscript{D} = 6.6 \times 10^{-8} when \(n_0 = 1500\).

5. Conclusion
This paper provides a rigorous comparison of two commonly used BER approximations for APD-based optical receivers. The analysis has been supported with examples and compared to the numerical BER found using the MGF approach. When ISI is dominant, the PI method overestimates the BER substantially and the PD method should be used instead. The BER of the PD method decreases exponentially with the optical energy in each bit while the BER computed using the simplified PI method saturates to a constant as the optical energy per bit increases. A closed-form expression was found for a threshold value, \(n_{th}\), for the average number of photons per 1 bit beyond which the PD method should be used instead of the PI method. As an example, the numerical calculations show that the BER of an optical receiver utilizing InP APD with a 100 nm multiplication layer, cannot be approximated with the PI method when the system speed exceeds 20 Gb/s.
