Abstract

Exciton and charge delocalization across π-stacked assemblies is of importance in biological systems and functional polymeric materials. To examine the requirements for exciton and hole stabilization, cofacial bifluorene (F2) torsionomers were designed, synthesized, and characterized: unhindered (model) MeF2, sterically hindered tBuF2, and cyclophane-like CF2, where fluorenes are locked in a perfect sandwich orientation via two methylene linkers. This set of bichromophores with varied torsional rigidity and orbital overlap shows that exciton stabilization requires a perfect sandwich-like arrangement, as seen by strong excimeric-like emission only in CF2 and MeF2. In contrast, hole delocalization is less geometrically restrictive and occurs even in sterically hindered tBuF2, as judged by 160 mV hole stabilization and a near-IR band in the spectrum of its cation radical. These findings underscore the diverse requirements for charge and energy delocalization across π-stacked assemblies.

Charge and energy dynamics across π‐stacked assemblies is of critical importance in biological systems as well in the performance of functional materials.1–3 Various π-stacked dimers capable of excimer formation and charge‐resonance stabilization based upon benzene,4–8 fluorene,9–12 pyrene,13, 14 and other aromatic donors15–18 have served as model systems to gain fundamental insight into key factors controlling charge/energy stabilization. These studies have established that the extent of the cationic charge (that is, hole) and exciton stabilization/delocalization is dependent on the orbital overlap between the chromophores, and is optimal when the π-stacked assembly adopts a perfect sandwich-like arrangement, where orbital overlap and electronic coupling are at their maxima.10, 11

Building upon this work, recent studies comparing a model covalently linked fluorene dimer F2 with the van der Waals dimer of fluorene, (F)n, have shown that the geometrical requirements for hole and exciton stabilization are distinct.19, 20 In particular, while their ionization potentials (IPs) are identical, excimeric emission at the sandwich-like geometries is shifted to longer wavelength in F2 as compared to (F)n. Thus, a slight displacement from the ideal overlap leads to a less stabilized excimer in (F)n, while cation radical stabilization remains unchanged. In the same context, in covalently linked polyfluorenes (Fn, n=2–7) the cationic charge is delocalized over multiple fluorenes,19, 20 while exciton delocalization is limited to two fluorenes.21

Importantly, the dynamics of hole and exciton transfer in Fn is modulated by a low‐frequency torsional mode between adjacent units, as evidenced in the broad and largely unresolved band in the gas‐phase excitation spectrum of F2.22 Indeed, calculations show that the activation barrier for interconversion between two mirror images displaced conformers of F2 is only 3 kcal mol−1, yet the electronic coupling along the interconversion coordinate varies between 0.0–0.3 eV (Figure 1 A).
Figure 1 A) The electronic coupling and relative energy of \( \text{F}_2 \) calculated using B1LYP40-D3/6-31G(d)+PCM(CH\(_2\)Cl\(_2\)) along the intrinsic reaction coordinate connecting two displaced conformations. The structure with the maximal coupling and energy is a transition state with the imaginary frequency (\( i 12.1 \text{ cm}^{-1} \)) corresponding to the torsional motion. B) Representation of the torsional mode in \( \text{F}_2 \). Incorporation of a methylene linker (\( \text{CF}_2 \)) and substituents (\( \text{MeF}_2 \) and \( \text{tBuF}_2 \)) produces various torsionomers of \( \text{F}_2 \).

To probe the effect of cofaciality on the hole and exciton stabilization in \( \pi \)-stacked systems, we synthesized three rigid torsionomers of \( \text{F}_2 \), that is, cofacial bifluorenes that differ by the extent of their cofaciality along the torsional coordinate via methylene linkers or substituents (Figure 1 B). In a cyclophane-like bifluorene \( \text{CF}_2 \), a pair of four-methylene linkers ensures that the relative arrangement of fluorenes is nearly identical to that found in the excimer and dimer cation radical of unsubstituted \( \text{F}_2 \). In contrast, bulky tBu groups in \( \text{tBuF}_2 \) guarantee that the sandwich-like arrangement is highly energetically unfavorable owing to increased steric hindrance. We then compare the redox and optoelectronic properties of the two torsionomers with those of model monomeric \( \text{MeF}_1/\text{tBuF}_1 \) and model bichromophoric \( \text{MeF}_2 \), the geometrical properties of which are nearly identical to those of unsubstituted \( \text{F}_2 \).

The bifluorene \( \text{CF}_2H2 \) precursor was generated by the condensation reaction between readily available\(^{22, 23} \text{CF}_2 \) and 0.5 equivalent of paraformaldehyde with potassium tert-butyl oxide catalyst (Scheme 1 A). Desired bi- and mono-fluorenes (that is, \( \text{CF}_2 \) and \( \text{CF}_1 \)) are readily produced through the methylation of \( \text{CF}_2H2/\text{CF} \) with Mel and potassium tert-butyl oxide as base (Scheme 1 A/B). Synthesis of \( \text{CF}_2 \) was carried out by following the procedure shown in Scheme 1 C. First, the intermediate \( \text{CF}_2H2 \) was generated by condensation of 2,7-dibromofluorene into \( \text{CF}_2H2 \) followed by its methylation. The bromide was then converted to a boron ester using Pd(dppf)Cl\(_2 \) catalyst, which was reacted with allyl bromide to produce \( \text{CF}_2 \). Intramolecular olefin metathesis reaction allowed us to prepare the \( \text{CF}_2 \) precursor in good yield, which was then subjected to Pd/C catalyzed hydrogenation, producing \( \text{CF}_2 \) as a final product. The \( \text{CF}_2 \) and \( \text{CF}_2 \) torsionomers and their model compounds \( \text{CF}_1 \) were fully characterized by \( ^1\text{H}/^1\text{C} \) NMR spectroscopy (Figure 2 A) and X-ray crystallography (Figure 2 B); see Supporting Information for full details.

The characteristic absorption bands in the electronic spectra of CF₂, MeF₂, and tBuF₂ are comprised of similar vibronic features and the wavelength of the absorption maximum is nearly invariant, that is, λ_max=272±2 nm (Figure 3). In contrast, emission spectra of F₂ derivatives display a strong dependence on the cofaciality between fluorene moieties (Figure 2). First, the emission spectrum of CF₂ shows a broad excimeric-like band at 402 nm with the lifetime (τ) of 3.8 ns. While the emission spectrum of MeF₂ displays a similar excimeric band at 400 nm (τ=6.5 ns), it also contains a weak band at 325 nm (τ=2.4 ns), which corresponds to the region where emission of MeF₁ monomer occurs (Supporting Information, Figure S3). This indicates that two minima must be present on the potential energy surface (PES) of the S₁ excited state of MeF₂. Indeed, TD-DFT calculations at the benchmarked B3LYP40-D3/6-31G(d)+PCM(CH₂Cl₂) revealed the presence of two equilibrium structures of MeF₂ on the excited state PES, with different exciton delocalization as represented by the transition-density plots in Figure 3. In the global-minimum excimeric sandwich-like structure, the exciton is delocalized over both fluorenes, while in the higher-energy displaced MeF₂, the exciton is localized on a single fluorene.
In contrast to unhindered MeF₂, the emission spectrum of sterically hindered tBuF₂ displays strong monomeric and weak excimeric bands at 325 and 380 nm, with corresponding lifetimes of 0.4 ns and 1.5 ns, respectively. This suggests that the steric hindrance imposed by the bulky tBu groups must destabilize a sandwich-like conformation in favor of the conformation where two fluorenes are displaced. Indeed, TD-DFT calculations showed the presence of two energetically similar equilibrium structures on the excited state PES of tBuF₂, corresponding to a sandwich-like conformation with exciton delocalized over both fluorenes and a displaced conformation with exciton fully localized on a single fluorene (Figure 3).

Cyclic voltammograms of cF₂, MeF₂, and tBuF₂ show (Figure 4 A) two reversible oxidation waves, with the first oxidation potential (E_ox) increasing gradually from 0.66 to 0.77 to 0.86 V vs. Fc/Fc⁺, respectively. Comparison with the appropriate model compounds (MeF₁ and tBuF₁) shows that stabilization of the cationic charge, that is, ΔE_ox = E_ox(cF₂)−E_ox(cF₁), is largest for cF₂ (ΔE_ox=360 mV) and decreases as the concomitant energetic penalty of adopting a sandwich-like arrangement increases in MeF₂ (ΔE_ox=250
mV) and \textit{t}BuF$_2$ ($\Delta E_{ox}=160$ mV). Despite the significant steric hindrance imposed by \textit{t}Bu groups in \textit{t}BuF$_2$, the hole stabilization of 160 mV remains significant, highlighting our prior finding that a hole can be stabilized even when there is a minimal orbital overlap.\textsuperscript{10, 11}

**Figure 4** A) Cyclic voltammograms of 2 mM \textit{t}BuF$_2$, MeF$_2$, \textit{t}BuF$_2$ (solid lines) and their corresponding monomeric model compounds (dashed lines) in CH$_2$Cl$_2$ (0.1 m n-Bu$_4$NPF$_6$) at a scan rate of 100 mV s$^{-1}$ and 22 °C. B) Electronic absorption spectra of \textit{t}BuF$_2^+$, MeF$_2^+$, and \textit{t}BuF$_2^+$ in CH$_2$Cl$_2$ at 22 °C. Sticks represent excitation wavelength calculated using TD-B1LYP40-D3/6-31G(d)+PCM(CH$_2$Cl$_2$); dark color corresponds to the sandwich-like structure and light color corresponds to the displaced structure of \textit{t}BuF$_2$.

We generated the cation radicals of \textit{Me}F$_2^+$, \textit{t}BuF$_2^+$, and \textit{t}F$_2^+$ via quantitative redox titrations using robust aromatic oxidants [THEO•][SbCl$_6$] and NAP•SbCl$_6$ (see details in the Supporting Information).\textsuperscript{27} Reproducible spectra of both \textit{t}F$_2^+$ and \textit{t}MeF$_2^+$ show a nearly identical intense inter-valence band centered at 1418 nm (Figure 4 B), signifying that the \textit{Me}F$_2^+$ structure is identical to that of \textit{t}F$_2^+$, that is, corresponding to a sandwich-like arrangement of fluorenes, and the cationic charge is delocalized over both fluorenes via strong through-space electronic coupling. Indeed, (TD)-DFT calculations confirmed that the intense near-IR band corresponds to sandwich-like conformations of \textit{t}F$_2^+$ and \textit{Me}F$_2^+$, where the charge/spin is delocalized over both fluorenes (Figure 4 B). Our calculations also predict a displaced conformation of \textit{Me}F$_2^+$ that lies 1.4 kcal mol$^{-1}$ higher in energy than the sandwich-like structure, and also displays spin/charge delocalization over both fluorenes, suggesting that even a minimal through-space orbital overlap is sufficient to promote hole delocalization in bifluorenes. This is in contrast to the excited state of \textit{Me}F$_2$, where in the displaced conformation the exciton is localized on a single fluorene (Figure 3).

The electronic spectrum of \textit{t}BuF$_2^+$ shows a much less intense inter-valence band that is shifted to longer wavelength (2400 nm), suggesting a reduced electronic coupling and/or increased reorganization energy in \textit{t}BuF$_2^+$ as compared to those in \textit{t}F$_2^+$ and \textit{Me}F$_2^+$. DFT calculations showed that two energetically
similar ($\Delta G = 3.5$ kcal mol$^{-1}$) conformations of $^{m\eta}$F2$^-$ may exist. The sandwich-like arrangement displays a significant puckering of the fluorene moieties owing to the steric hindrance from bulky tBu groups, yet the spin/charge remains delocalized over both fluorenes. In the displaced $^{m\sigma}$F2$^-$, the spin/charge is largely localized on a single fluorene, due to the significant displacement and therefore reduced orbital overlap/electronic coupling.

Additional insights come from gas-phase spectra of the three torsionomers, obtained via laser induced fluorescence (LIF) spectroscopy using a heated supersonic nozzle; details are provided in the Supporting Information. As shown in Figure 5, the differences in these spectra are striking. The spectrum of $^{m\eta}$F2 (green) is similar to that of F2 (black) in displaying a broad and largely unresolved profile; the breadth is explained in the terms of an underlying progression in the torsional motion which is broadened by the fast dynamics and strong modulation of the electronic coupling (Figure 1A). The underlying progression is clearly seen in the spectrum of $^{m\sigma}$F2 (blue), absent any spectral broadening. On the other hand, the spectrum of $^{c}$F2 (red) is both sharp and distinct, and strikingly red-shifted. Here, the torsional libration is quenched and the Franck–Condon active vibration corresponds to a “breathing” type motion of the two subunits (see Figure S14 in Supporting Information). The dramatic consequences of steric hindrance in the $^{m\eta}$F2 derivative can be further seen in a comparison with unsubstituted F2 (Figure 5, pale blue vs. black). Here, the underlying torsional progression is clearly evidenced, as the breadth of the spectra is similar. A more detailed analysis of these spectra is beyond the scope of this article and will be reported in future.

![Figure 5](image)

*Figure 5* Laser-induced fluorescence spectra of $^{m\eta}$F2 (green), $^{m\sigma}$F2 (blue), $^{c}$F2 (red), and F2 (black) in the gas-phase. Sharp transitions in the spectrum of $^{m\eta}$F2 reflect monomeric impurity. Comparison of the LIF spectra of F2 (black) with $^{m\sigma}$F2 (blue) shows the underlying torsional progression.

In conclusion, we have used a set of novel torsionomers to examine the contrasting requirements for exciton and hole stabilization in π-stacked assemblies. Exciton stabilization requires a perfect sandwich-like arrangement, as evidenced by the presence of strong excimeric-like emission only in $^{c}$F2 and $^{m\eta}$F2. In contrast, cationic charge can be delocalized even for structures where the path to cofaciality is sterically hindered, that is, $^{m\eta}$F2, as judged by the 160 mV hole stabilization and the
presence of a near-IR transition in its cation radical spectrum. These findings underscore important design principles for next generation optoelectronic materials.
