Abstract

Children with severe [osteogenesis imperfecta](#) (OI) typically experience numerous fractures and progressive skeletal deformities over their lifetime. Recent studies proposed finite element models to assess fracture risk and guide clinicians in determining appropriate intervention in children with OI, but lack of appropriate material property inputs remains a challenge. This study aimed to characterize macroscopic anisotropic [cortical bone](#) material properties and investigate relationships with [bone density](#) measures in children with severe OI. Specimens were obtained from tibial or femoral shafts of nine children with severe OI and five controls. The specimens were cut into beams, characterized in bending, and imaged by [synchrotron radiation](#) X-ray micro-computed [tomography](#). Longitudinal modulus of elasticity, yield strength, and bending strength were 32–65% lower in the OI group ($p < 0.001$). Yield strain did not differ between groups ($p \geq 0.197$). In both groups, modulus and strength were lower in the transverse direction ($p \leq 0.009$), but anisotropy was less pronounced in the OI group. Intracortical vascular porosity was almost six times higher in the OI group ($p < 0.001$), but no differences

were observed in [osteocyte](#) lacunar porosity between the groups ($p = 0.086$). Volumetric bone [mineral density](#) was lower in the OI group ($p < 0.001$), but volumetric tissue mineral density was not ($p = 0.770$). Longitudinal OI bone modulus and strength were correlated with volumetric bone mineral density ($p \leq 0.024$) but not volumetric tissue mineral density ($p \geq 0.099$). Results indicate that cortical bone in children with severe OI yields at the same strain as normal bone, and that their decreased bone material strength is associated with reduced volumetric bone mineral density. These results will enable the advancement of fracture risk assessment capability in children with severe OI.

Osteogenesis imperfecta; Pediatric bone; Material properties; Synchrotron radiation micro-computed tomography; Fracture risk

1. Introduction

[Osteogenesis imperfecta](#) (OI) is a genetic [bone fragility](#) disorder affecting between 1/20,000 and 1/5000 births ([Byers and Steiner, 1992](#), [Marini, 2011](#)). There is no cure, and individuals are affected throughout their lifetime. OI type III, the most severe phenotype in individuals surviving birth, typically results in numerous bone fractures and progressive skeletal deformities, such as pronounced bowing of long bones ([Sillence et al., 1979](#)). [Clinical management](#) usually involves antiresorptive drugs and [physical rehabilitation](#). Corrective surgery is sometimes used to straighten a bowed [tibia](#) or femur with the aim to improve mobility and prevent fracture. However, there is no quantitative method by which to assess fracture risk or the potential benefit of surgical or rehabilitative interventions in children with OI. Recent studies proposed using finite element models to quantify tibial and femoral fracture risk in children with OI ([Fritz et al., 2009a](#), [Fritz et al., 2009b](#), [Caouette et al., 2014](#), [Caouette et al., 2016](#)). These models could prove useful to clinicians in determining safe activity levels or when to perform corrective surgery. However, a major challenge to these fracture risk assessment efforts remains the paucity of macroscopic-scale material property data in children with severe OI.

Macroscopic bone material properties have been studied in small groups of children with OI ([Albert et al., 2013](#), [Albert et al., 2014](#), [Vardakastani et al., 2014](#), [Imbert et al., 2015](#)). Bone material strength and modulus of elasticity were confirmed to be reduced in these children compared to controls ([Imbert et al., 2015](#)). Abnormally elevated intracortical vascular porosity was also observed in children with OI (Jameson [Jameson et al., 2013](#), [Pazzaglia et al., 2013](#), [Albert et al., 2013](#), [Albert et al., 2014](#), [Imbert et al., 2015](#)), and was found to have a negative effect on [cortical bone](#) modulus and strength ([Albert et al., 2014](#), [Vardakastani et al., 2014](#), [Imbert et al., 2015](#)). These studies, however, were not focused specifically on children with severe OI, who tend to experience the most fractures, and only one study ([Albert et al., 2014](#)) examined anisotropy (i.e., directional dependence) of the bone material properties.

The objectives of the current study were to: (1) characterize the anisotropic material properties of cortical bone in children with severe OI at the macroscopic scale; (2) compare these properties to those of [pediatric](#) controls; and (3) investigate relationships between material properties and measures of bone material density in this patient population. The results of this study will enable improved fracture risk assessment capabilities in children with severe OI.

2. Materials and methods

2.1. Bone specimens

Nine cortical [osteotomy](#) specimens were collected from the tibial or femoral diaphyses of seven children and adolescents (age 1–16 years) with severe OI (OI group), [Table 1](#). Six of these children were diagnosed with OI type III. The seventh (donor 7) has a less common recessive form, OI type VIII, with clinical severity similar to that of OI type III. These specimens were obtained during routine surgical procedures at [Shriners Hospitals for Children](#) – Chicago under informed consent/assent and an approved IRB protocol (Western IRB WIRB#20160453, Marquette University #HR-2167). The specimens were fresh-frozen and stored below -20°C prior to testing.

Table 1. Specimen description and donor details. For each specimen, the numbers of machined beams tested of each orientation relative to the long bone axis, *i.e.*, longitudinal (*L*) or transverse (*T*), is indicated. Of those beams, a subset (*numbers in parentheses*) was imaged by SR μ CT following mechanical testing.

a Specimens OI 2 and OI 3 were obtained from contralateral femurs of the same donor (donor 2) during a bilateral corrective procedure.

b Specimens OI 7 and OI 8 were obtained from a single donor (donor 6) during surgical procedures that took place eight months apart.

c All specimens were obtained from the long bone mid-diaphysis, with the exception of specimen OI 5, which was obtained from the proximal region of the femur diaphysis.

For comparison, [cortical bone](#) specimens were obtained from the femoral and tibial diaphyses of five deceased donors (control group, age 8–11 years, cause of death unknown).

2.2. Specimen preparation

Each specimen was cut into 2–12 rectangular beams ([Table 1](#)) using a precision sectioning saw (IsoMet™ Low Speed Saw, Buehler®, Lake Bluff, IL, USA) and a 0.3 mm-thick diamond blade (IsoMet 15HC Model 11-4244, Buehler®, Lake Bluff, IL, USA). The beams were 5–6 mm long, with the long beam axis being either parallel to the long diaphyseal axis (longitudinal beams) or in the circumferential direction of the outer cortex (transverse beams) (Albert [et al., 2013](#)). Beam depth ($0.633 \text{ mm} \pm 0.042 \text{ mm}$) and base ($1.021 \text{ mm} \pm 0.039 \text{ mm}$) were measured with a digital micrometer (Model 293-340, Mitutoyo Corporation, Japan).

2.3. Mechanical testing

The beams were tested in three-point bending on a custom-designed jig using methodology validated for small bone specimens (Albert [et al., 2013](#)). A span length of 4.0 mm was chosen to accommodate the small osteotomy specimens collected for this study. Mechanical testing was performed on an electromechanical testing machine (Model 3345, Instron®, Norwood, MA, USA) with a 50 N load cell (Model 2519-102, Instron®, Norwood, MA, USA). The test was controlled using Bluehill 2 Software (Instron®, Norwood, MA, USA). Beam deflection at mid-span was determined as the vertical displacement of the loading nose relative to the supports, measured with a linear variable differential transformer (Model 2601-092, Instron®, Norwood, MA, USA). Five cycles of pre-conditioning (0.05–0.5 N) were applied at a crosshead displacement rate of 0.2 mm/min, followed by a ramp to failure at a constant beam deflection rate of 2.0 mm/min. The beams were kept hydrated during the test using a

drop of buffered saline, which remained in place on the tensile surface of the beam by surface tension for the duration of the test (less than 2 min). Load, crosshead displacement, and beam deflection were sampled at 100 Hz. Mid-span stress and strain at the tensile surface of the beam were calculated from the load and deflection data ([ASTM-D790-07, 2006](#); Albert [Albert et al., 2013](#), [Albert et al., 2014](#)). The following material properties were calculated from the stress-strain data obtained during the ramp to failure using Matlab (R2012a, Mathworks, Natick, MA, USA), correcting for shear effects (see [Supplement - Shear Effects Correction](#)): bending strength, yield strength, modulus of elasticity, and yield strain.

2.4. Synchrotron radiation X-ray micro-computed tomographic imaging (SR μ CT)

After mechanical testing, cortical [bone density](#) and porosity measures were obtained for a subset of beams ([Table 1](#)) using SR μ CT (Beamline 8.3.2, Advanced Light Source, Lawrence Berkeley National Laboratory, Berkeley, CA, USA). These methods were described in detail in earlier works ([Jameson et al., 2013](#); [Albert et al., 2014](#)). In short, each scan consisted of 1025 [radiographs](#) collected at a monochromatic beam energy of 17 keV over a continuous 180° rotation using a pco.edge sCMOS camera (PCO-TECH Inc., Romulus, MI, USA). The camera was mounted to a high resolution [X-ray microscope](#) (Optique Peter, Lentilly, France) containing a 10× objective lens (Mitutoyo Corporation, Kawasaki, Japan) and a 50 μ m thick lutetium aluminum garnet ($\text{Lu}_3\text{Al}_5\text{O}_{12}$) [scintillator](#) to convert X-rays into visible light. This configuration resulted in a 1.7 mm \times 1.4 mm field of view, with an isotropic imaged pixel size of 0.65 μ m. [Tomographic reconstruction](#) of each scan was performed with Octopus 8.6 software (inCT, Ghent, Belgium), resulting in a 32-bit grayscale dataset with 2160 slices each having 2560 \times 2560 pixels.

Visual inspection of these scans revealed the presence of a small region of microdamage resulting from mechanical testing, extending approximately 0.25 mm on either side of the test-induced fracture ([Fig. 1](#)). Imaging measurements were obtained within a 0.6 mm³ rectangular prismatic region of interest located at least 0.5 mm away from the fracture site to exclude the region in which test-induced microdamage was present ([Fig. 1](#)).

Fig. 1. Scan of representative beam in the OI group (specimen OI 5). (A) Longitudinal [radiographic](#) view of a beam obtained from specimen OI 5, where the test-induced fracture can be seen (see small white arrows) and the region containing microdamage extends approximately 0.25 mm on either side of the fracture, *i.e.*, between lines 1 and 2. (B) Reconstructed image of a cross-section adjacent to the test-induced fracture, where microdamage can be seen (see bold white arrow). (C) Cross-section obtained within the region of interest, approximately 0.5 mm away from the middle of the test-induced fracture (*i.e.*, below line 3), where no microdamage was visible.

The total porosity in each beam was calculated as the sum of the contributions from both vascular and [osteocyte](#) lacunar porosities. In accordance with the established nomenclature ([Parfitt et al., 1987](#), [Cooper et al., 2003](#)), the vascular porosity was defined as the canal volume per tissue volume ($Ca.V/TV$) and included Haversian canals, Volkmann canals, and resorption spaces ([Cardoso et al., 2013](#)). The osteocyte lacunar porosity was defined as the lacunar total volume per tissue volume ($Lc.TV/TV$). These porosity contributions were determined using Fiji software ([Schneider et al., 2012](#)), a distribution of ImageJ v1.49f (National Institutes of Health, Bethesda, MD, USA) and the plug-in BoneJ ([Doubé et al., 2010](#)). Pores having a volume $<82 \mu\text{m}^3$ were considered as noise and removed, while pores with a volume $>2000 \mu\text{m}^3$ were assumed to be part of the vascular porosity. These limits were based on previous laser scanning [confocal microscopy](#) and SR μ CT studies in human bone ([McCreadie et al., 2004](#), [Carter et al., 2013](#), [Dong et al., 2014](#)). Due to the monochromatic [X-ray source](#), bone density measures were calculated for each beam from: (1) the 32-bit gray values, which corresponded directly to the linear attenuation coefficients; and (2) the X-ray mass attenuation coefficient of bone, $(\mu/\rho)_{bone}$, which is a material constant that depends on X-ray beam energy. According to reference tables provided by the National Institute of Standards and Technology, $(\mu/\rho)_{bone}$ is equal to $6.41 \text{ cm}^2/\text{g}$ at 17 keV ([Hubbell 1982](#)).

Volumetric bone [mineral density](#), $vBMD$, was determined by dividing the mean linear attenuation coefficient of the total volume within the beam (*i.e.*, including both bone and porosity voxels) in the scanned region of interest by $(\mu/\rho)_{bone}$. Volumetric tissue mineral density, $vTMD$, was evaluated by

segmenting out all non-bone voxels from the original volume using a histogram-based threshold ([Ridler and Calvard, 1978](#)), calculating the mean linear attenuation coefficient of the remaining bone voxels, and dividing this number by $(\mu/\rho)_{bone}$. The X-ray beam energy was calibrated prior to imaging using silver and germanium foils, which have known peaks in [X-ray absorption](#) at 25.514 keV and 11.103 keV, respectively. The energy resolution of the beam varies by less than 1% ([MacDowell et al., 2012](#)). Three-dimensional visualizations of the imaging datasets were performed using the Volume Rendering module in Avizo 9.2.0 software (FEI, Hillsboro, OR, USA).

2.5. Statistical analysis

Statistical analysis employed linear mixed models with specimen number as a random factor and likelihood ratio tests for investigating statistical significance. The random effect of specimen number was one-dimensional Gaussian for analyses of mechanical properties (longitudinal and transverse properties were analyzed separately) and two-dimensional Gaussian for analyses of imaging measures (analyses of imaging parameters combined beams of both orientations). P-values smaller than 0.05 were considered statistically significant. Linear mixed model analyses were performed to compare the material properties and imaging measures between the groups of specimens (OI vs. control group), and the material properties between different beam orientations (longitudinal vs. transverse) within each group. Similarly, linear mixed models were used to explore associations between mechanical properties (dependent variables) and the imaging measures (independent variable) in children with OI, controlling for possible clustering within specimen by including a specimen random effect.

3. Results

3.1. Material properties

Average material properties for each specimen are presented in [Table 2](#). Properties are compared between the two groups (OI vs. control) and between beam orientations (longitudinal vs. transverse) in [Table 3](#).

Table 2. Longitudinal (*L*) and transverse (*T*) material properties of [cortical bone](#) in children with severe OI (OI group) and [pediatric](#) controls (control group). Mean (standard deviation) for each specimen.

Note: standard deviation is presented when a minimum of three beams were tested for the specimen.

Table 3. Comparison of [cortical bone](#) material properties between children with severe OI (OI group) and [pediatric](#) controls (control group) tested in the longitudinal vs. transverse directions. Mean (standard error). P-values based on linear mixed models. Elastic modulus and strength were lower in children with OI vs. controls.

Material property	OI group	Control group	P-value (OI vs. control)
<i>Modulus of elasticity (GPa)</i>			
Longitudinal	5.4 (0.5)	13.2 (0.7)	<0.001
Transverse	3.4 (0.6)	5.0 (0.6)	0.061
P-value (longitudinal vs. transverse)	<0.001	<0.001	

Material property	OI group	Control group	P-value (OI vs. control)
<i>Yield strength (MPa)</i>			
Longitudinal	59 (5)	149 (7)	<0.001
Transverse	31 (7)	51 (7)	0.055
P-value (longitudinal vs. transverse)	<0.001	<0.001	
<i>Yield strain (%)</i>			
Longitudinal	1.1 (0.0)	1.1 (0.1)	0.893
Transverse	0.9 (0.0)	1.0 (0.0)	0.197
P-value (longitudinal vs. transverse)	0.009	<0.001	
<i>Bending strength (MPa)</i>			
Longitudinal	86 (9)	244 (11)	<0.001
Transverse	42 (10)	79 (10)	0.015
P-value (longitudinal vs. transverse)	<0.001	<0.001	

P-values in bold font emphasize the comparisons that are statistically significant (P-values <0.05).

In both groups, the properties exhibited anisotropy (Table 3). Modulus of elasticity, yield strength, yield strain, and bending strength were lower in the transverse vs. longitudinal directions ($p \leq 0.009$). The effect of beam orientation (*i.e.*, anisotropy) on these properties, however, was less pronounced in the OI group. For example, the average ratio of longitudinal to transverse modulus, calculated as the average of the ratios obtained per specimen, was 2.6 for the control group but only 1.6 for the OI group. Similarly, the average ratio of longitudinal/transverse yield strength was 2.9 in the control group but only 1.9 in the OI group.

Between the two groups of donors, longitudinal modulus, yield strength, and bending strength, were significantly lower in the OI group, as was transverse bending strength ($p \leq 0.015$, Table 3). These properties were on average 47–65% lower in the OI group vs. controls. Transverse modulus and yield strength were also lower in the OI group, although these differences were not statistically significant ($p \geq 0.055$). No significant difference in yield strains were observed between the groups ($p \geq 0.197$).

3.2. Bone density

Visualization of the beam specimens indicated a high degree of variability in [cortical bone](#) structure within the OI group, with some beams displaying numerous small intracortical pores and others showing large pores that occupied over 50% of the beam volume. SR μ CT scans from representative longitudinal beams within each group are illustrated in [Fig. 2](#).

Fig. 2. [Synchrotron radiation](#) X-ray micro-computed tomographic scans of [cortical bone](#) structure from longitudinal beam specimens. Top Left: femur specimen from an 11 year-old male control donor (specimen C 5; bone volume fraction $V_f = 0.94$). Top Right: [tibia](#) specimen from a 13 year-old female with severe OI and high V_f (specimen OI 6; $V_f = 0.96$). Lower Left: femur specimen from 3 year-old female with severe OI and intermediate V_f (specimen OI 3; $V_f = 0.71$). Lower Right: femur specimen from an 11 year-old male with severe OI and low V_f (specimen OI 5; $V_f = 0.44$). Double-sided arrows indicate the orientation of the osteons. Scale bars represent 0.5 mm. See [Video 1](#), [Video 2](#), [Video 3](#), [Video 4](#) for 3 D visualization of each of these scans.

On average, vBMD was 22% lower in the OI group vs. controls ($p \leq 0.001$), [Table 4](#). The vTMD, on the other hand, did not differ between the groups ($p = 0.770$). Average total porosity was 29.81% in the OI group, compared to 6.18% for the controls ($p < 0.001$). Average vascular porosity was nearly six times higher in the OI vs. control group, *i.e.*, 28.76% vs. 5.03%, respectively ($p < 0.001$). Lacunar porosity, however, did not differ significantly between the groups ($p = 0.086$).

Table 4. [Cortical bone](#) density and porosity measures for each group. Total porosity is decomposed in to vascular (Ca.V/TV) and [osteocyte](#) lacunar (Lc.TV/TV) contributions. Means (standard errors) and p-values based on linear mixed models with specimen random effect.

Imaging parameter	OI group	Control group	P-value (OI vs. control)
<i>vBMD</i> (gHA/cm ³)	0.77 (0.04)	0.99 (0.04)	<0.001
<i>vTMD</i> (gHA/cm ³)	1.05 (0.02)	1.04 (0.02)	0.770
Total porosity (%)	29.81 (3.49)	6.18 (3.90)	<0.001
Ca.V/TV (%)	28.76 (3.45)	5.03 (3.88)	<0.001
Lc.TV/TV (%)	1.51 (0.10)	1.24 (0.11)	0.086

3.3. Relationships between bone material properties and imaging measures in OI
 Relationships between longitudinal bone material properties and the imaging measures are presented in [Table 5](#) and [Fig. 3](#). Longitudinal modulus of elasticity and both strength measures were correlated positively with *vBMD* ($p \leq 0.024$) but no significant association was observed between material properties and *vTMD*. Modulus of elasticity and strength tended to decrease with increasing total porosity, but the relationships were not found to be statistically significant ($p \geq 0.062$). Finally, yield strain was not significantly correlated with any imaging parameter.

Table 5. Relationships between longitudinal mechanical properties and bone imaging measures (volumetric bone [mineral density](#) *vBMD*, volumetric tissue mineral density *vTMD*, and total intracortical porosity) in children with severe OI based on simple linear regression analysis. Modulus of elasticity and strength were positively correlated with *vBMD* but not with *vTMD*. Adjusted R² were obtained from a simple linear regression model.

Mechanical property	Density measure (predictor)	Intercept (SE)	Slope (SE)	P-value for the slope	Adjusted R ²
Modulus of elasticity (GPa)	<i>vBMD</i> (gHA/cm ³)	0.01 (1.76)	6.70 (2.37)	0.010	0.30
	<i>vTMD</i> (gHA/cm ³)	-3.66 (6.42)	8.19 (6.17)	0.159	0.06

a Note that negative R² indicates that the model contains some non-significant terms that do not improve the prediction properties.

Fig. 3. Relationship between longitudinal modulus of elasticity and volumetric bone volume fraction in the OI group. A simple linear regression with R² is superposed to the linear mixed model.

4. Discussion

Children with severe OI typically experience multiple fractures over their lifetime. Recent research has been aimed at enabling fracture risk assessment in these children by finite element modeling ([Fritz et al., 2009a](#), [Fritz et al., 2009b](#), [Caouette et al., 2014](#), [Caouette et al., 2016](#)), with the goal of developing and improving preventive treatments to reduce fracture occurrences. However, lack of appropriate macroscopic-scale anisotropic material property inputs for these models remains a major challenge to these efforts. This study characterized the anisotropic macroscopic material properties of [cortical bone](#) from tibial and femoral diaphyses of children with severe OI, compared these properties to those of controls, and explored relationships between OI bone material properties and bone material density measures.

Bending tests are used commonly for bone material characterization. When testing small bone specimens in bending, special attention should be given to beam dimensions. Modulus of elasticity of

bone measured in bending tends to be lower when beam depth is smaller than 500 μm ([Choi et al., 1990](#)), therefore a beam depth of approximately 600 μm was selected for this study. A minimum span/beam depth ratio of 16 or 20 is sometimes recommended to avoid error resulting from shear effects ([ASTM-D790-07, 2006](#), [Wallace et al., 2014](#)). In this study, a span of 4 mm was chosen to accommodate the small [osteotomy](#) specimens available, providing a span/depth ratio of approximately seven; hence the effect of shear deformation was accounted for when calculating the material properties.

[Bone density](#) measures ([Table 4](#)) and longitudinal material properties ([Table 2](#), [Table 3](#)) for the control group were similar to values reported previously for [pediatric](#) cortical bone ([Hirsch and Evans, 1965](#), [Currey and Butler, 1975](#), [Currey and Pond, 1989](#), [Ohman et al., 2011](#), [Jameson et al., 2013](#), [Imbert et al., 2015](#)). Results in the OI group ([Table 2](#), [Table 3](#), [Table 4](#)) were also comparable to values reported in earlier studies of cortical bone in children with mild to severe OI ([Albert et al., 2014](#), [Vardakastani et al., 2014](#), [Imbert et al., 2015](#)). In contrast to these earlier OI studies, the current study is focused more specifically on a group of children with severe OI, who tend to experience the most fractures. To the authors' knowledge, this paper additionally presents the first anisotropic measures of bone material strength and macroscopic modulus of elasticity in "normal" pediatric bone.

Bone material properties were anisotropic in both groups ([Table 3](#), longitudinal vs. transverse comparisons); however, anisotropy was less pronounced in the children with OI vs. controls. This reduced anisotropy in OI bone material properties may be a result of abnormalities at the ultra-structural level, such as reduced collagen content ([Camacho et al., 1999](#)), reduced spacing between collagen fibrils ([Bart et al., 2014](#)), and/or bone mineral crystals being smaller and less organized ([Traub et al., 1994](#), [Fratzl et al., 1996](#)).

Compared to pediatric controls, modulus and strength measures in both directions were substantially lower in the OI group ([Table 3](#)). Although the differences in transverse modulus and yield strength between the groups were not found to be significant, it is possible that statistical significance may have been obtained with larger sample sizes. Interestingly, yield strain did not differ between the groups. These observations indicate that cortical bone in children with OI yields at a similar strain as normal bone, but this occurs under lower stress due to their lower modulus of elasticity.

Compared to controls, average vBMD was 22% lower and total porosity almost five times higher in the OI group ([Table 4](#)). These findings are consistent with other recent studies in which elevated intracortical porosity was observed in long bone shafts of children with OI (Jameson [Jameson et al., 2013](#), [Pazzaglia et al., 2013](#), [Albert et al., 2014](#), [Vardakastani et al., 2014](#)). vTMD, however, did not differ significantly between the groups. This finding was surprising since abnormally elevated mineralization density has been observed in the [iliac crests](#) of children with OI ([Boyde et al., 1999](#)). It is possible that vTMD may have been lower at the surgical (diaphyseal) sites from which the specimens in the current study were obtained, where bowing was present and elevated bone modeling and remodeling activity was likely. However, in another recent study using a laboratory-based microcomputed [tomography](#) system with a polychromatic [X-ray source](#), pediatric OI bone specimens obtained during similar procedures were reported to have slightly (10%) higher vTMD than controls ([Imbert et al., 2014](#)). The reason for these differing observations is not clear but may be attributed to differences in anatomic sites and testing methodologies. Nonetheless, the reduced vBMD observed in the long bone shafts of

children with severe OI appears to be a consequence of their elevated intracortical porosity rather than decreased vTMD.

Relationships have been established between bone material properties and density measures in human trabecular and cortical bone ([Carter and Hayes, 1976](#), [Keller, 1994](#), [Keyak et al., 1994](#), [Morgan et al., 2003](#)). Current results confirmed that modulus of elasticity and strength decrease with decreases in vBMD in the long bone shafts of children with severe OI ([Table 5](#)). These relationships indicate that vBMD may be useful in estimating [bone properties in vivo](#) in the long bone shafts of children with OI. Further research is therefore warranted to determine whether volumetric bone mineral density measurements obtained at clinical scan resolutions (*e.g.*, by peripheral quantitative computed tomography) would enable appropriate estimation of cortical bone material properties in these children. In light of the increased intracortical porosity compared to controls ([Table 4](#)) and the negative (although not quite significant) relationship observed between bending strength and total porosity in the OI group ([Table 5](#)), it appears that a porous cortex contributes to long bone shaft fracture risk in children with severe OI. Increased intracortical porosity can reduce bone material strength substantially by decreasing the amount of bone material carrying the physiological loads and acting as [stress risers](#) ([Currey, 1962](#), [Yeni et al., 1997](#)).

The bone material properties, on the other hand, were not related to vTMD. Thus, it appears that reduced bone material strength in children with severe OI is attributed primarily to the reduced quantity of [bone tissue](#) present within the cortical bone material rather than to inferior quality of the tissue. Nonetheless, the current study examined only two mineral parameters (*i.e.*, vBMD and vTMD). It is possible that other factors, such as microdamage ([Hernandez et al., 2014](#)), mineral size, shape, and arrangement ([Cassella et al., 1995](#), [Boskey, 2003](#)), and/or collagen structure and crosslink density ([Gautieri et al., 2009](#)), also affect bone material strength in this population.

In normal pediatric bones, increases in modulus and strength occur between early childhood and adolescence ([Currey and Butler, 1975](#)). In the current study, however, bone material strength and modulus did not appear to increase with age in the children with severe OI. Nonetheless, due to limited sample size and other factors that could affect bone properties over time (*e.g.*, decreased physical activity ([Takken et al., 2004](#), [Sousa et al., 2014](#)) and/or [bisphosphonate](#) treatments ([Mashiba et al., 2000](#))), a definitive conclusion cannot be made at this time regarding relationships between cortical bone properties and age in children with severe OI.

Bisphosphonates are used commonly in the treatment of children with severe OI. These therapies have been associated with increased [bone mass](#) in the spine and reduced fracture occurrence in these children ([Glorieux et al., 1998](#), [Rauch et al., 2003](#), [Bishop et al., 2010](#), [Dwan et al., 2014](#)). Their effect on cortical bone tissue quality in children with OI is not yet clear. Bisphosphonates can lead to decreased cortical bone material strength due to their impairment of cortical bone remodeling ([Mashiba et al., 2000](#), [Brock et al., 2015](#)). However, abnormally elevated intracortical vascular porosity within the long bone shafts of children with OI ([Pazzaglia et al., 2013](#), [Albert et al., 2014](#)) may enable new bone formation in cortical regions in spite of decreased osteoclastic activity. Thus, increases in cortical vBMD and bone material strength may be possible during this treatment. Nonetheless, further research is warranted to assess the effects of bisphosphonate therapies on cortical bone material properties in this patient population.

In conclusion, the main findings of this study are summarized as follows. In children with severe OI:

- (1) Cortical bone material strength and modulus of elasticity are considerably lower than normal.
- (2) Cortical bone exhibits anisotropic macroscopic material properties, but this anisotropy is less pronounced than in normal bone.
- (3) Cortical bone yields at the same strain as do “normal” pediatric bones.
- (4) Intracortical porosity is increased and vBMD is decreased, but vTMD is similar to that of pediatric controls.
- (5) Cortical bone material strength and modulus of elasticity are correlated positively with vBMD but not with vTMD.

Acknowledgements

The authors thank Kathy Reiners (Shriners Hospitals for Children – Chicago) for coordinating the OI bone specimen collection, and Dr. Cathy Carlson (University of Minnesota) for her help in procuring the normal [pediatric](#) control specimens. We are grateful for the assistance of beamline scientists Dr. Dula [Parkinson](#) and Dr. Alastair MacDowell (Advanced Light Source ALS, Lawrence Berkeley National Laboratory) in collecting the imaging data. We also thank Dr. Stephen M. Heinrich (Marquette University) for guidance on accounting for shear deformation in analyzing the mechanical data.
