Abstract

Purpose.

Microaneurysms (MAs) are considered a hallmark of retinal vascular disease, yet what little is known about them is mostly based upon histology, not clinical observation. Here, we use the recently developed adaptive optics scanning light ophthalmoscope (AOSLO) fluorescein angiography (FA) to image human MAs in vivo and to expand on previously described MA morphologic classification schemes.

Methods.

Patients with vascular retinopathies (diabetic, hypertensive, and branch and central retinal vein occlusion) were imaged with reflectance AOSLO and AOSLO FA. Ninety-three MAs, from 14 eyes, were imaged and classified according to appearance into six morphologic groups: focal bulge, saccular, fusiform, mixed, pedunculated, and irregular. The MA perimeter, area, and feret maximum and minimum were correlated to morphology and retinal pathology. Select MAs were imaged longitudinally in two eyes.

Results.

Adaptive optics scanning light ophthalmoscope fluorescein angiography imaging revealed microscopic features of MAs not appreciated on conventional images. Saccular MAs were most prevalent (47%). No association was found between the type of retinal pathology and MA morphology ($P = 0.44$). Pedunculated and irregular MAs were among the largest MAs with average areas of 4188 and 4116 μm$^2$, respectively. Focal hypofluorescent regions were noted in 30% of MAs and were more likely to be associated with larger MAs (3086 vs. 1448 μm$^2$, $P = 0.0001$).

Conclusions.

Retinal MAs can be classified in vivo into six different morphologic types, according to the geometry of their two-dimensional (2D) en face view. Adaptive optics scanning light ophthalmoscope fluorescein angiography imaging of MAs offers the possibility of studying microvascular change on a histologic scale, which may help our understanding of disease progression and treatment response.

Keywords: microaneurysm, AOSLO, fluorescein angiography
Introduction

Initially described in diabetes, MAs appear as manifestations of a wide range of systemic and retinal diseases, including ischemic, infectious, inflammatory, hematologic, and radiation-related disorders.1–5 Retinal MAs have been shown to be an important sign in the progression of systemic disease,6–12 and they have been used as components of multiple retinopathy severity classification schemes.13–16 Microaneurysm counting17–21 and dynamic turnover22–25 studies have revealed associations linking MAs to increased retinopathy, suggesting that even a single MA may have predictive value.26 Furthermore, clinical imaging has demonstrated that MAs are correlated with extravascular leakage and vision loss.23,27

Despite their clinical significance, the pathogenesis and natural history of individual MAs remains poorly understood. Histologic studies using India ink infusion and trypsin digest techniques have investigated the role of pericytes,28,29 lipid and hyaline infiltration,2–30 neovascularization,31 and endothelial disruption32 in attempts to understand MA formation and progression. The relationship between the MA wall and lumen has been investigated using trypsin digest processing,33 electron microscopy,34 and confocal scanning laser microscopy with von Willebrand factor staining.35 One recent study has suggested that MA radius-to-associated-vessel-diameter ratio may be a useful metric for stratifying risk of leakage,36 helping to explain why some smaller MAs lead to leakage while some larger ones do not. As treatment modalities advance to target individual MAs with laser therapy,37 the ability to determine which MAs are at higher risk for leakage or rupture is increasingly valuable. However, since most MA knowledge is derived from post mortem histopathology, we currently have a very limited understanding of the dynamics of MA development and natural progression in vivo.

Advances in retinal imaging have increased our ability to image the retinal vasculature, including the development of time-differential fundus photography,38–40 optical coherence tomography (OCT),41–46 and entoptic viewing.47–49 A recent study using spectral-domain OCT (SD-OCT) was able to extract basic MA dimensions through diameter measurements.50 The correction of the ocular monochromatic aberrations using adaptive optics, when added to the fundus camera,51,52 scanning light ophthalmoscope (AOSLO),53–57 and OCT (AO-OCT),58,59 has further improved our capacity to study healthy and diseased microvasculature anatomy. Recently, we demonstrated that in vivo imaging of the healthy human retinal microvasculature could be
performed with safe light levels by combining AOSLO with fluorescein angiography (AOSLO FA).  

Studying MAs with the resolution of AOSLO technology has the potential to reveal helpful information about their formation, natural progression, and response to treatment. In this manuscript, we use AOSLO FA to expand upon previous MA classification schemes and to introduce qualitative and quantitative metrics to describe MA geometry in vivo. Using the complementary aspect of AOSLO reflectance imaging, we investigated MA capillary wall and lumen relationships as well as regions of MA and capillary nonperfusion. The associations between MA morphology, size, and luminal fluorescence were evaluated statistically.

**Methods**

**Human Subjects**

To ensure that the MA classification scheme presented here was comprehensive and applicable to different pathologies, subjects with various vascular retinopathies and ophthalmic treatment histories were recruited. Ophthalmic diagnoses were established for each patient based upon review of their medical records by New York Eye and Ear Infirmary ophthalmologists. The presence of retinal MAs had been previously documented by color fundus photography (Topcon 3D OCT 2000; Topcon Corporation, Tokyo, Japan) and/or standard FA (Topcon 3D OCT 2000; Topcon Corporation; Optos P200; Optos plc, Dunfermline, Scotland; and Heidelberg Spectralis HRA-OCT; Heidelberg Engineering, Inc., Heidelberg, Germany). Following discussion of the nature and possible consequences of the study, informed written consent was obtained from each subject. This study adhered to the tenets of the Declaration of Helsinki and was approved by the institutional review board of the New York Eye and Ear Infirmary.

**AOSLO Imaging Protocol**

Mydriasis and cycloplegia were achieved by instillation of one drop of 2.5% phenylephrine hydrochloride ophthalmic solution (Bausch & Lomb, Inc., Rochester, NY) and one drop of 1% tropicamide ophthalmic solution (Akorn, Inc., Lake Forest, IL). Ocular axial length measurements were collected (IOL Master; Carl Zeiss Meditec AG, Jena, Germany) in order to calculate the scale of the AOSLO images.
using the Emsley schematic eye model. The AOSLO used in this study was a modified version of the one originally described by Dubra and Sulai with the addition of a 488-nm light source, an emission filter centered at 525 nm, and a 45-nm transmission bandwidth. The subjects were positioned in front of the instrument using a dental impression made with dental putty (Splash! Putty; DenMat Holdings, LLC, Lompoc, CA) on a bite bar mounted on a translation stage. Fine adjustments of the stage allowed for stable and repeatable alignment of the subject's pupil with the entrance pupil of the AOSLO (7.75 mm in diameter). Subjects were instructed to direct their gaze toward an internal fixation target that was moved until the desired region of interest was within the AOSLO field of view. These areas, all located within 15° from the center of the fovea, contained microangiopathic features previously identified on color fundus photography and/or standard FA. The reflectance channel was used to scout important regions to be examined with the fluorescence channel following fluorescein administration.

Adaptive optics scanning light ophthalmoscope fluorescein angiography imaging was performed using our previously described protocol, after administering fluorescein at 20 mg/kg of body weight in 50 mL of orange juice. Imaging was initiated at 15 minutes following ingestion. Simultaneous image sequences of fluorescence and reflectance images, consisting of up to 500 frames each, were recorded at 15 frames/s using either a 1.0°, 1.5°, or 1.75° field of view. Subjects were given short breaks at regular intervals and encouraged to blink frequently to maintain normal tear film. Imaging sessions concluded once all regions of interest had been imaged, the patient tired, or the image signal waned. No imaging session extended longer than 45 minutes. The feasibility of studying MA dynamics was explored through longitudinal imaging at 1-month intervals in two subjects.

**Light Safety**

During AOSLO imaging, the retina was simultaneously scanned with three light sources, with wavelengths centered at 488, 790, and 850 nm. These light sources were coaxial and entered the eye with collimation accounting for the longitudinal chromatic aberration of an average eye. The three beams overlapped producing a square raster, 30% larger than the imaged area, using a 14.5-KHz horizontal resonant optical scanner (Electro-Optical Products Corporation, New York, NY) and a 16-Hz vertical scanner (Physik Instrumente, Karlsruhe, Germany). Synchronous modulation of the light sources

---

[ Investigative Ophthalmology and Visual Science, Vol. 55, No. 3 (March 2014): pg. 1299-1309. DOI. This article is © Association for Research in Vision and Ophthalmology and permission has been granted for this version to appear in e-Publications@Marquette. turned them on at the beginning of each horizontal line used for imaging when scanning from left to right. As a result, only the central portion of the scanning raster was exposed to light. The optical powers without modulation (i.e., continuous wave) measured at the cornea were 15 μW for the 850-nm wavefront sensing superluminescent diode (SLD; Superlum, Carrigtwohill, Ireland), 210 μW for the 790-nm imaging SLD (Superlum), and 32 μW for the 488-nm diode laser (Lasos, Lasertechnick GmbH, Jena, Germany). During imaging, the on/off modulation reduced the average powers delivered by approximately 75%. No retinal location was exposed to the combined light sources for longer than 120 seconds. All sources were considered as lasers for calculating maximum permissible exposure (MPE) under the American National Standards I (ANSI) Z136.1 2000 guidelines. These imaging parameters, as described above, resulted in light exposures six times below both the photochemical and the thermal MPE limits. In order to avoid any possibility for light or fluorescein toxicity, repeat imaging sessions were performed after at least a 7-day interval.

**Image Processing**

The reflectance image sequences, collected using 790-nm light, were used to estimate eye motion in order to create a single registered average image with high signal-to-noise ratio from each image sequence. The AOSLO reflectance and fluorescence images included in this manuscript were created in this manner, using sequences of 32 to 100 frames after compensation of the warping due to the sinusoidal motion of the resonant scanner. Registered images were manually tiled (Adobe Photoshop CS6; Adobe Systems, Inc., San Jose, CA) to create larger montages of the retinal vasculature, as needed.

**Microaneurysm Classification**

The qualitative morphologic classification of MAs proposed in this work is an extension of the scheme suggested by Moore et al. Reflectance AOSLO images were often obscure in subjects with extensive vascular pathology, preventing interpretable visualization of vascular features, while AOSLO FA was often able to clarify these complex vascular relationships. The variation in longitudinal chromatic aberration across individuals prevented both reflectance and fluorescence images from being in focus at the same time for all subjects.
There were 93 MAs identified and classified according to their two-dimensional (2D) geometry in the en face AOSLO FA images (Fig. 1), as follows:

1. Focal bulge were defined as MAs where the combined width of the associated capillary and MA was less than twice the width of an adjacent nonaffected region of the capillary. All other morphologies represented MAs where the combined width of the associated capillary and MA was more than twice the width of an adjacent nonaneurysmal region.

2. Saccular MAs were defined as those with asymmetric dilatations with at least 75% of the total area of the MA on one side of the central axis of the associated capillary.

3. Fusiform MAs were defined as symmetrically dilated MAs around their associated capillary, with less than 75% of the total area of the MA on either side of the associated capillary.

**Figure 1** Proposed expanded anatomical classification of MAs as seen with conventional fluorescein angiography (left) and AOSLO FA (center) with corresponding illustrated examples (right). All images have been contrast stretched. Scale bar: 50 μm.
4. Mixed saccular/fusiform were defined as MAs that could not be
categorized as either saccular or fusiform and it was uncertain
which capillary was associated with it, or when the orientation of
the MA prevented a clear en face view.
5. Pedunculated MAs were asymmetric MAs tethered to their
associated capillary via a tapered narrowing of the lumen.
6. Irregular MAs were saccular, fusiform, or pedunculated with a
nonconvex shape (note: a convex shape is one in which the line
segment defined by any two points within it is fully contained
within the shape). For pedunculated MAs, this definition
excludes the region associated with the tapered narrowing of
the lumen and applies to the remainder of the aneurysm.

As MA features appear different in AOSLO FA and reflectance
images, comparing the two techniques allows inferences to be made
about capillary walls and perfusion. Reflectance AOSLO images
typically reveal the capillary and MA wall, while AOSLO FA shows
exclusively the intraluminal, perfused space. Accordingly, AOSLO
reflectance images were used to locate nonperfused capillaries, which
did not appear in AOSLO FA. With AOSLO FA, the presence of focal
hypofluorescent regions within the otherwise highly fluorescent lumen
of the MA was recorded.

Three trained examiners familiar with the MA classification (Fig. 1)
independently graded all 93 MAs. Based on their classifications,
terrexaminer agreement was quantified by calculating the Fleiss'
kappa reliability coefficient.65

Microaneurysm Geometry Quantification

The boundaries of all 93 MAs were manually segmented on the
2D AOSLO FA images using custom MATLAB (Mathworks, Natick, MA)
software. The area, perimeter, feret maximum (longest intraluminal
diameter of MA), and feret minimum (longest diameter perpendicular
to feret maximum) of these boundaries were then calculated (Fig. 2).
Traditionally, MA measurements have frequently used width of the
aneurysm along the direction perpendicular to the associated capillary.
That requires identifying, with certainty, the capillary associated with
each MA and determining the location and extent of that capillary's
connection with the MA, which is not always possible. Feret maximum
(max) and minimum (min) were therefore selected instead, as they
can be more readily measured even when information surrounding the
associated capillary was not clear.
Figure 2 Adaptive optics scanning light ophthalmoscope fluorescein angiography image of saccular MA (A) with schematic (B) depicting manual boundary segmentation of aneurysm in order to determine area (within red dotted lines), perimeter (red dotted line), feret max (thin arrow), and feret min (thick arrow). Scale bar: 50 μm.

Correlations between metrics, primary ophthalmic diagnoses, and morphologies were studied by performing a two-step analysis. First, ANOVA tests were used to test whether there were significant differences among the metrics derived from each of the conditions and morphologies. When these tests showed significance ($P < 0.05$), then the Scheffe’s post hoc test was used to evaluate the differences between each possible pair of variables examined.

Interobserver segmentation reliability was assessed by having three trained, independent examiners segment the boundary of 14 randomly selected MAs. Then, intraclass correlation of their measurements was calculated.
Results

Patient Demographics

Included in this study were 13 subjects (7 men, 6 women; mean age 52.8 years; range, 44–68 years) from various racial/ethnic backgrounds (Table 1). Ophthalmic diagnoses, included diabetic retinopathy (DR) in six patients, central retinal vein occlusion (CRVO) in four patients, branch retinal vein occlusion (BRVO) in two patients, and hypertensive retinopathy (HTN) in one patient. One DR subject had imaging performed in both eyes.

Table 1 Patient Demographics
PRP, pan-retinal photocoagulation.

Morphology and Pathology

Among the six morphologies, saccular MAs were the most prevalent, followed by focal bulge, fusiform, mixed, irregular, and pedunculated, respectively (Table 2). No relationship was seen between systemic pathology and MA morphology (ANOVA, \( P = 0.44 \)). This is consistent with the fact that even when imaging a relatively small retinal area affected by a single pathology, as shown in Figure 3, multiple types of MAs were simultaneously present. Interobserver morphology identification agreement among the three readers was high (kappa coefficient: 0.88).
Figure 3 Montage of AOSLO FA images, showing the foveal capillary network and the foveal avascular zone (FAZ) in the right eye of a subject with hypertension. Microaneurysms of various size and morphology are visible. Red dots indicate arterioles. Blue dots indicate venules. Scale bar: 300 μm.

Wall and Lumen

Imaging using AOSLO reflectance and FA provide complementary information about capillary wall and lumen (Fig. 4). The combination of these imaging modalities revealed that, even within a single eye affected by a single condition, MAs with varying degrees of wall thickening and fluorescence could be observed (Fig. 5, subject with CRVO). Reflectance AOSLO imaging can also reveal evidence of nonperfused capillaries and obliterated MAs that cannot be visualized with AOSLO FA imaging alone (Fig. 6).
Figure 4  Adaptive optics scanning light ophthalmoscope reflectance (A) and fluorescence (B) images of an irregular MA, nasal to FAZ in Figure 3. The superposition of these images ([C], with [B] in red) shows the relationship between wall and lumen. Scale bar: 100 μm.

Figure 6 Reflectance AOSLO images (left) and AOSLO FA (right) of pathologic regions in a patient with CRVO reveal various states of MAs. Hyperfluorescent saccular and fusiform MAs (A2) were visualized in a region without additional pathology (A1). Asterisks (B1, C1) indicate thickened vascular walls that were seen in both hyperfluorescent MAs (B2) and a hypofluorescent MA (C2). Arrows (C2, D2) indicate intraluminal hypofluorescence. Carets (D1, D2) depict location of small MAs that do not fluoresce on AOSLO FA. Scale bar: 100 μm.

Pathology and MA Geometrical Metrics

Interobserver segmentation reliability among the three readers was high (intraclass correlation: 0.99). There was a significant difference between the mean metric values estimated for MAs from each disease (Table 3) for area ($P = 0.05$, ANOVA), perimeter ($P = 0.04$, ANOVA), feret max ($P = 0.05$, ANOVA), and feret min ($P = 0.05$, ANOVA). Further analysis using the Scheffe test, summarized in Table 4, failed to find statistically significant differences between all possible pairs of systemic pathologies. Statistical significance ($P < 0.05$) and near statistical significance ($0.05 < P < 0.10$) was found only between CRVO and DR for perimeter, feret max, and feret min. Bubble graphs (Fig. 7A) show the similarity of quantitative metrics between pathologies.
Figure 7 Graphs comparing quantitative metrics (area versus perimeter) for pathologies (A) and morphologies (B). Center point of each ellipse represents area mean (x-axis) and perimeter mean (y-axis). Horizontal extent of ellipses determined by area mean ± SD. Vertical extent of ellipses determined by means of perimeter ± SD.

**Morphology and MA Geometrical Metrics**

Among the six MA morphologies, there were significant difference between their mean measurements of area \((P = 0.0001, \text{ANOVA})\), perimeter \((P = 0.0001, \text{ANOVA})\), feret max \((P = 0.0001, \text{ANOVA})\), and feret min \((P = 0.0001, \text{ANOVA})\) (Table 5). Further analysis using the Scheffe test (Table 6), found differences between several pairs of morphologies. Several statistical significant \((P < 0.05)\) and nearly statistically significant \((0.05 < P < 0.10)\) results were found for the greater perimeter, feret max, and feret min of pedunculated and irregular MAs as compared with the other morphologies. Bubble graphs (Fig. 7B) show the differences of quantitative metrics between morphologies.

Y greater than X, statistically significant results bolded, nearly statistically significant results italicized.
Intraluminal Hypofluorescent Regions Versus Morphology and Quantitative Metrics

Adaptive optics scanning light ophthalmoscope fluorescein angiography images revealed intraluminal hypofluorescence in 28 out of 93 (30.1%) MAs (Fig. 1, AOSLO FA fusiform, irregular, pedunculated; Fig. 4B; Figs. 5C2, 5D2, boxes). This hypofluorescence was never found in focal bulge MAs (0%), often found in saccular (25%), fusiform (30%), mixed (50%), and pedunculated (50%), and most frequently in irregular MAs (75%). Microaneurysms with hypofluorescent regions were statistically (ANOVA) larger in area (3086 vs. 1448 μm², \( P = 0.0001 \)), perimeter (358 vs. 209 μm, \( P = 0.0001 \)), feret max (121 vs. 73 μm, \( P = 0.0001 \)), and feret min (96 vs. 54 μm, \( P = 0.0001 \)). Although there was no correlation between systemic pathology and intraluminal hypofluorescence (ANOVA, \( P = 0.68 \)), there was a strong correlation between the presence or absence of hypofluorescent regions and the various morphologies (ANOVA, \( P = 0.0001 \)).

Longitudinal Imaging

A fusiform retinal MA (Fig. 8, left column) in a subject with hypertensive retinopathy (Fig. 3) was shown to remain unchanged over a 4-month period (variability of each metric was <±2% throughout). An adjacent retinal region, imaged only at time 0 and again after 4 months (Fig. 8, middle column), shows an MA with mixed shape that dramatically increased in size adjacent to a focal bulge MA that regressed over the same time. Imaging in a subject with CRVO before and after anti-VEGF injection shows regression of a mixed MA that was sustained 3 months later (Fig. 8, right column), while an adjacent, saccular MA remained stable.
Figure 8 Left and center columns from one subject with hypertensive retinopathy; right column from one subject with CRVO. Left column shows AOSLO FA images of a fusiform MA with stable boundaries at four different imaging sessions over a 4-month period. Center column follows a mixed MA with growth between time 0 (perimeter: 162 μm, area: 1702 μm², feret max: 52 μm, feret min: 57 μm) and a second imaging session at 4 months (perimeter: 230 μm, area: 3676 μm², feret max: 63 μm, feret min: 77 μm). The initial image shows a focal bulge MA in the upper right corner that appears to have regressed by the later session. Right column depicts a region with saccular (perimeter: 145 μm, area 1415 μm², feret max: 52 μm, feret min: 39 μm) and mixed MAs (perimeter: 120 μm, area 1030 μm², feret max: 40 μm, feret min: 35 μm) imaged before and after anti-VEGF treatment (asterisk indicates treatment had occurred 3 weeks prior). The mixed MA regressed and continued to be hypofluorescent at an additional follow-up imaging session while the saccular MA remained stable. Scale bar: 100 μm. ND, no data.

Discussion

Emerging high-resolution ophthalmic imaging modalities such as AOSLO and motion contrast OCT are allowing for the visualization of retinal capillaries with unprecedented transverse and axial resolution. When used to image retinas affected by vascular disease, AOSLO FA reveals MAs with great detail, permitting a rich morphologic categorization scheme. The retinal MA classification presented in this work is based on the en face, 2D geometry of MAs. It incorporates the saccular, fusiform, and focal bulge designations proposed in previous studies, as well as three additional morphologies discernable with AOSLO FA. Although our proposed classification is based on AOSLO FA images, it can be applied to MA images acquired using other modalities, such as emerging motion contrast techniques.

This study is limited by the relatively small number of MAs from 13 patients representing a variety of retinal conditions and ophthalmic treatment histories. Additionally, our analysis attempted to classify MAs, which are three-dimensional (3D) structures, based solely upon their 2D, en face appearance. This may have limited our accuracy in geometrical assessment and will need to be validated using additional techniques. Three-dimensional imaging modalities with isotropic or near-isotropic resolution (e.g., AO-OCT) might help to reveal additional complexities of MA structure, including the nature of mixed morphology MAs. With all of these limitations considered, the data resulting from the classification and boundary-derived metrics provides a number of interesting, early findings.

The first observations derived from statistical testing was that retinal pathology appeared to place no limits or bias to development of MA morphology, and that multiple, if not all, MA morphologies can be found within an adjacent, small area of an individual retina. Thus, while assaying for the presence of MAs may be a sensitive tool for following retinal pathology, MA morphology does not seem to have a propensity for any vasculopathy. Consistent with a previous study in DR, we found that saccular MAs were more prevalent than fusiform and focal bulge morphologies; this trend applied not only to DR, but also to the subjects with CRVO, BRVO, and HTN.

An initial ANOVA test indicated that the mean metric values are different among the retinal conditions tested in this work \((P = 0.04–0.05)\). However, Scheffe tests used to evaluate differences in metric values between any pair of pathologies only showed that diabetic MAs had statistically greater \((P < 0.05)\) mean perimeter and feret max than CRVO MAs. Thus, based on the metrics used in this study, there are few obvious differences between MAs due to retinal pathology. In contrast, the different types of MA morphologies show several, more statistically significant differences in some cases, including the relatively greater size of irregular and pedunculated morphologies and the smaller dimensions of the focal bulge MAs. This is expected as the classification itself is, like these metrics, based on the MA geometry. Future studies will be needed to further elaborate on the differences between the pathologies and morphologies presented here.

A recent study by Wang et al. found no correlation between MA leakage and lumen diameter, wall diameter, or wall thickness, suggesting that increasing size may not lead to increased risk of leakage. Ezra et al. found that the physical relationship between the MA radius and associated vessel wall may contribute to leakiness in
saccular MAs. Several neuroradiology studies have found that multilobular intracranial aneurysms are more likely to rupture than unilobular aneurysms,\textsuperscript{70–72} with one group determining that aneurysm neck diameter and not overall aneurysm size was more important in determining the risk of rupture.\textsuperscript{73} These studies indicate that size alone is not a sufficient predictor for course of MA pathology, and that other metrics may need to be identified. It is likely that a deeper understanding of MA morphology may help determine the risk of leakiness or rupture.

In addition to determining boundaries, AOSLO FA reveals intraluminal hypofluorescent regions within some larger MAs. These regions, not readily observable using conventional FA, appeared in almost one-third of the imaged MAs, irrespective of the underlying retinal condition. Notably, such hypofluorescent areas were absent in focal bulge MAs, but appeared in the majority of the pedunculated and irregularly shaped ones. Histologic studies have revealed that MA lumens can be infiltrated by a variety of cell types, ranging from acute inflammatory cells such as polymorphonuclear cells and monocytes to red blood cell breakdown products and cellular debris.\textsuperscript{34} The hypofluorescence we observed could represent such luminal clots. The greater luminal surface area of larger MAs like the pedunculated and irregular morphologies may produce more turbulent blood flow, which may increase the risk of endothelial injury and the formation or enlargement of luminal clots. Further studies are needed to elucidate the relationship between these hypofluorescent regions and advanced disease.

The complementary information provided by reflectance AOSLO and FA imaging proved useful in evaluating wall thickness and identifying nonperfused capillaries and MAs. The different perspective provided by each imaging modality was helpful in exploring MA natural progression. This was further examined via imaging a few MAs longitudinally (Fig. 8), demonstrating that AOSLO FA can show MA stability, growth, and resolution as well as potentially evaluate the efficacy of various treatments. The observation of MAs in various stages of resolution only a few microns apart on the same capillary illustrates a complex dynamic at play. While the regression of an MA following anti-VEGF treatment (Fig. 8, right column) is encouraging, it remains to be seen whether the regression was due to treatment or just coincident to natural history. As such, monitoring a small sample of MAs, or their turnover, may not accurately portray all possible patterns of progression or treatment response. With additional work beyond this preliminary study, the AOSLO FA may prove to be a
powerful tool in studying the treatment effects of anti-VEGF interventions on MAs.

Combining a robust qualitative classification with quantitative metrics may allow us to better stratify MAs clinically in terms of risk of leakage or rupture and associated capillary dropout. Clinical applications of this approach may prove useful in better understanding microvascular disease progression and help point the way to more successful treatment regimes.
